MR. RUPERT FARRANT, whose untimely death last week, at the age of 36, came as a shock to his many friends, was a man of singularly winning personality and great ability. He was educated at the Westminster Hospital, and studied also at King's College and St. Bartholomew's. After qualifying M.R.C.S. and L.R.C.P. in 1906, he held a good many resident posts at his own and other hospitals, eventually becoming Surgical Registrar at Westminster. He obtained the Fellowship of the Royal College of Surgeons in 1909. He was specially interested in the ductless glands, and did a great deal of research work on thyroid function in health and disease, in the laboratory of Professor Cushman at University College and elsewhere. His assiduity in the collection and examination of thyroids from cases of disease of all kinds from asylums, infirmaries, and hospitals, was remarkable. He formulated a theory of a correlated cycle of changes in the histological appearances and functional activity of the gland under the influence of toxins, and was particularly interested in the relation between deficient thyroid action and some forms of insanity.

Rupert Farrant saw active service throughout the war at Gallipoli, in Egypt, Mesopotamia, and in France, where he gained the Military Cross. He suffered severely from trench fever and was seriously injured by a shell explosion. While still in France he was elected to the honorary staff

of the Westminster Hospital, and took over his duties as soon as he was demobilized. His health was, however, much impaired, and though the renal trouble left by the trench fever got better, he never recovered completely from the shell concussion. Feeling himself unable to carry out his duties as he would have liked, he resigned his appointment some months ago, and had been resting in the country up till the last.

ARTHUR JACKSON, F.R.C.S. ENG.,
Shrewsbury.

WE regret to announce the death, on January 9th at Shrewsbury, of Mr. Arthur Jackson.

Born at Grays, Essex, in 1855, son of the late Daniel Jackson, of Chadwell Place, Grays, he was educated at Brentwood, whence he proceeded to St. Bartholomew's. He qualified in 1878 and became F.R.C.S. Eng. in 1882. After holding resident appointments at St. Luke's Hospital, London, and at Beckett Hospital, Barnsley, he went to Shrewsbury, where in 1884 he joined the late Mr. J. R. Humphreys, then senior surgeon at the Salop Infirmary, in partnership. He was appointed surgeon to the Salop Infirmary in 1890, the other surgeons being H. J. Rope, who died twenty years ago, and Mr. W. Edlowes, now living in retirement at Bath. Those were difficult days in the hospital surgical world, when the Listerian system of wound treatment was only being tardily recognized, and Mr. Jackson, as an ardent supporter of the new principles, had much hard work to accomplish. He also witnessed, as the result of the new surgery, the invasion of many new areas of work, and was a keen disciple of such men as Mayo, Horsley, Freyer, and Moynihan. A bold and resourceful surgeon, Mr. Jackson soon acquired a very large consulting practice in Shropshire and the adjoining counties of Mid Wales, where his energy and quiet determined manner made him always the friend in need of his country brethren.

He was surgeon also to the Newtown Infirmary, Montgomeryshire, and to the Wenlock and Brosely Hospitals in Shropshire, and to the Bicton Asylum and the Tuberculosis Sanatorium at Shirleot. Notwithstanding these hospital appointments with their many urgent calls, it was often remarked that he always seemed to have time to attend to the individual matter in request, and that he never refused help nor seemed to be hurried—no one ever applied to him in vain. He was for many years a great supporter of the British Medical Association. He was president of the local Branch in 1899, when he read a paper on "Diseases of the breast," which contained much closely reasoned observation and carefully deduced indications for treatment.

During the war stress of work fell heavily upon Mr. Jackson. He was due to retire from his arduous duties as senior surgeon to the Royal Salop Infirmary in 1915, but at the request of his colleagues he willingly consented to remain at his post, and only vacated it in November, 1919. Early in December last he had received by telegram the sad news of the sudden death in India of his only son, Arthur H. Conway Jackson, I.C.S. He was thus, stricken with grief, little able to withstand the onset in the first week of the new year of an attack of influenza of a virulent nature, complicated by double pneumonia.

He married Florence Eleanor, youngest daughter of the late Rev. S. Sunderland, Vicar of Penistone, Yorkshire, by whom, together with a daughter, he is survived. A memorial service was held at St. Chad's Church, Shrewsbury, on January 12th, which was very largely attended by his professional brethren from far and near, and he was afterwards laid to rest in the general cemetery, in a certain part where lie several of his former fellow-workers.

MANY readers will be grieved to hear of the death of Dr. EDWARD COLLINS BOUSFIELD, which took place suddenly on January 7th, from the rupture of an unsuspected aneurysm. He had had several serious illnesses in recent years, some of them contracted in the pursuit of his pathological duties. He devoted the times of convalescence to sea voyages, and in this way he visited the East and West Indies and Africa. He returned from his last voyage in good health, and we were hoping for years more of fruitful work. He studied at St. Bartholomew's Hospital, and qualified L.R.C.P., M.R.C.S., in 1878. He spent a number

of years in general practice in the Old Kent Road, doing a good deal of research work at the same time. He was an early authority on photomicrography, and wrote a useful manual upon the subject. On his appointment to the position of bacteriologist to the metropolitan boroughs of Camberwell and Hackney and director of the Camberwell Research Laboratories he went to reside at Denmark Hill, where he remained to the end. He leaves a widow and three sons and a daughter. The youngest son is also in the medical profession, and is, we understand, carrying on with the old staff his father's work at Camberwell. Dr. Bousfield had a striking personality, and all who knew him set a high value on his friendship. He was a keen investigator, having an alert mind, a well balanced judgement, a thirst for truth, and a special aptitude for the practical application of new knowledge.

The Services.

HONOURS.

MENTIONS IN DISPATCHES.

THE names of the following officers have been brought to the notice of the Secretary of State for War by Lieut.-General Sir J. A. L. Haldane, General Officer Commanding-in-Chief, Mesopotamian Expeditionary Force, for distinguished and gallant services and devotion to duty, and are recommended for special recognition:—Captains: W. Adams, R.A.M.C.(S.R.), L. G. Blackmore, R.A.M.C.; R. R. Thun Oo Tha, I.M.S.; Sub-assistant Surgeons: Abdulmua Ahmedia Bukhari and Hashim Ali Khan, I.M.D.

DEATHS IN THE SERVICES.

Major James Sydney Pascoe, D.S.O., R.A.M.C., died in the Military Hospital at Poona on December 29th, aged 43. He was the fourth son of the Rev. S. Pascoe of Newquay, was educated at Charing Cross Hospital, and took the M.R.C.S. and L.R.C.P.Lond., in 1904. After holding a house-surgeoncy at Charing Cross, he entered the army as lieutenant in 1905, and attained the rank of major on October 15th, 1915. He served in the South African war in 1900-1902, in the Imperial Yeomanry, taking part in the Orange Free State and in the Transvaal, at Wittebergen, and gained the Queen's medal with four clasps. In the late war he was twice mentioned in dispatches, in the *London Gazette* of May 29th, 1917, and for the Indian frontier campaign on July 10th, 1919, received the 1914 star, with the war medal and Victory medal, the D.S.O. on June 3rd, 1917, and the Legion of Honour (Chevalier) on February 24th, 1915.

COMMITTEE ON POST-GRADUATE MEDICAL EDUCATION IN LONDON.

As we go to press the composition is announced of the Committee appointed by the Minister of Health, with the concurrence of the University Grants Committee, to formulate a scheme for post-graduate instruction in medicine in London.

The terms of reference are: "To investigate the needs of medical practitioners and other graduates for further education in medicine in London, and to submit proposals for a practicable scheme for meeting them."

The Chairman, as stated in the *JOURNAL* this week, at page 170, is the Earl of Athlone, G.C.B. The other members of the Committee are Dr. H. J. Cardale, Chairman of the London Panel Committee; Sir Wilmot Herringham, K.C.M.G., M.D., a member of the University Grants Committee; Sir George Makins, G.C.M.G., late President of the Royal College of Surgeons of England; Sir George Newman, K.C.B., M.D., Chief Medical Officer, Ministry of Health, and Board of Education; Sir Robert Newman, Bt., M.P. for Exeter; Sir Edward Penton, K.B.E., a member of the board of the Middlesex Hospital; Sir E. Cooper Perry, M.D., Principal Officer of the University of London; Mr. J. Dill Russell, F.R.C.S., late honorary secretary of the Hampstead Division of the British Medical Association; and Dr. T. W. Shore, Dean of St. Bartholomew's Hospital and Medical School. The secretary is Mr. A. L. Hetherington, to whom all communications should be addressed at the Ministry of Health, Whitehall, S.W.

DR. JOSEPH CATES, M.O.H. for the county borough of St. Helens, has been appointed county M.O.H. for Surrey. Dr. G. S. TRAIL, on the occasion of his retirement after forty-three and a half years' active practice at Strichen, Aberdeenshire, has been presented with an inscribed silver salver, a gold watch chain, and a cheque for £130 by the inhabitants of the district.

VITAL STATISTICS FOR ENGLAND AND WALES, 1920.

We are indebted to the Registrar-General for the following statement showing the birth rates and death rates and the rates of infantile mortality in England and Wales and in certain parts of the country during 1920.

ENGLAND AND WALES.

Birth Rate, Death Rate, and Infant Mortality during the Year 1920 (Provisional Figures).

	Birth Rate per 1,000 Total Population.	Death Rate per 1,000 Population (Crude Rate).*	Deaths Under One Year per 1,000 Births.
England and Wales	25.4	12.4	80
96 great towns, including London (populations ex- ceeding 50,000 at the Census of 1911)	26.2	12.5	85
148 smaller towns (popu- lations from 20,000 to 50,000 at the Census of 1911)	24.9	11.3	80
London	26.3	12.4	75

* The death rate for England and Wales relates to the whole population, but that for London and the groups of towns to the civilian population only.

The rates here shown are provisional, but any adjustment that may be found necessary will not affect the following points, namely: (1) That the birth rate for 1920 is the highest of the decade; (2) that the death rate is the lowest ever recorded; (3) that the infant mortality is the lowest ever recorded; (4) that the number of births is the highest ever recorded; (5) that the number of deaths is the lowest recorded since 1862, when the population was only 20 millions.

Medical News.

THE Ministry of Health has issued an amended notice with regard to substitutes for salvarsan which local authorities may supply to practitioners and the prices that may be paid. The names of the substances are: Arsenobillon and novarsenobillon (Messrs. May and Baker), diarsenol and neodiarsenol (Messrs. Allen and Hanburys), galyol (The Anglo-French Drug Company), kharsivan and neokharsivan (Messrs. Burroughs, Wellcome and Co.), and salvarsan (Messrs. Evans, Sons, Lescher and Webb).

PROFESSOR H. R. KENWOOD, C.M.G., will give an introductory lecture on Monday, January 31st, at 5.30 p.m., to students attending the courses of instruction at the Royal Sanitary Institute.

THE annual dinner of past and present students of the Royal London Ophthalmic Hospital will be held at the Café Royal, Regent Street, on Thursday, February 10th, at 7 for 7.30 o'clock. The chair will be taken by Mr. J. B. Lawford, Consulting Surgeon to the Hospital. Tickets, price 15s. (excluding wine), may be obtained from Mr. Charles Goulden, 42, Welbeck Street, W.1.

A SERIES of six post-graduate lectures and demonstrations in connexion with the Manchester Babies' Hospital will be held on Saturdays at 3.30 p.m., commencing February 5th. There is no fee for attendance.

THE annual dance of the Medical Society, University College Hospital, will be held in the Medical School Library on Monday, February 7th, from 9.30 to 2.30. Tickets, 15s., may be had from Mr. W. L. Spencer-Cox, honorary secretary, at the hospital.

DR. GEOFFREY EVANS has been appointed Assistant Director of the Medical Professorial Unit at St. Bartholomew's Hospital, and Assistant Physician to the Hospital. This appointment completes the staff of the unit, Dr. Francis Fraser having already succeeded Sir Archibald Garrod in the post of Director.

A SPECIAL meeting of the Council of King Edward's Hospital Fund for London was held on January 26th to consider the policy to be recommended to the Government for the preservation of the voluntary system of hospital management and control. The specific resolutions contained in a report of the Executive Committee were unanimously adopted, and ordered to be forwarded to the Prime Minister, the Minister of Health, and the members of the Government Committee of Inquiry into Hospital Finance.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 422, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 422, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Antiology*.

MANAGER
telephone.

2630, Gerrard.

3. MEDICAL SECRETARY, *Medizeca*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the

6, South Frederick Street, Dublin
telephone, 4757, (Dublin), and of

Square, Edinburgh (telegrams: Associate, Edinburgh; telephone, 4361, Central).

QUERIES AND ANSWERS.

INCITAMIN OR FISCHER'S SOLUTION.

A CORRESPONDENT asks whether incitamin, an organic preparation devised by Professor Fischer of Copenhagen, is to be obtained in this country.

An article, in which Professor J. F. Fischer, an x-ray specialist in Copenhagen, described his solution, to which he has given the name "incitamin," although it is also known as Fischer's solution, was published in the *Ugeskrift for Læger*, the journal of the Danish Medical Association, on December 2nd, 1920. According to this article the solution contains carbolic acid, serum and saliva (both in a modified form), and extract of pancreatic gland. Professor Fischer states that these ingredients are obtained from calves and horses, that the solution is colourless or faintly yellow and slightly cloudy, and that a deposit which formed on standing did not indicate any diminution in its potency. He tested its stability by keeping it for some time in a thermostat, and he has convinced himself that it is not toxic, provided it is properly applied. Originally he intended to continue his investigations of this preparation in modest obscurity, but he has changed his mind and put the preparation on the market, because he considered the final stage of its evolution had been reached, and that it was desirable that it should be manufactured under adequate supervision and on a large scale in order that it might be available to many investigators. It is prepared by the "Serpens" company, and is now obtainable from chemists in Denmark, but Professor Fischer does not mention the price. Much of his paper is concerned with clinical reports of hospital cases in which incitamin was used as a dressing for wounds and ulcers. In one of these cases a large ulcerating cancer of the back of the hand was treated, first with radium and then with x rays; the new growth was replaced by deep and extensive ulceration, which seemed an even more pressing indication for amputation than the original condition; the report of the case goes on to relate the triumph of incitamin. Almost equally dramatic are other records, several of which are of cases of varicose ulcer. The lay press in Denmark seized on this publication, hailing incitamin as the dawn of a new era, and so on. The incident drew from Dr. J. S. Möller a protest (*Ugeskrift for Læger*, December 16th) under the heading "A New Arknum." He writes: "Professor Fischer cannot have wholly forgotten that throughout the past years there has been waged a constant war through *Ugeskrift for Læger* against secret remedies, a war, the provisional fruits of which are to be found in recent legislation. . . . He must not, therefore, be surprised if one who has taken part in this war squirms when he reads the last number of *Ugeskrift* and the howl of advertisement which has gone up from the press." The same number of *Ugeskrift* contains a reply by Professor Fischer and a rather halting defence of the policy of the journal by the editors. No one familiar with conditions in Denmark and the high esteem in which the editors of *Ugeskrift* are held by their

colleagues will question the motives by which they have been actuated in this matter, but it cannot be denied that the position brought about is unfortunate. The medical profession in this country may well await fuller and more precise information before using the solution.

BRILLE TYPE FOR BLIND CHILDREN.

DR. ROBERT A. WELSH of Felton has under his care a child, aged 8, with an acquired hydrocephalus, first noticed at the age of 2 years. Five years ago, after a series of convulsions, the sight was lost. There is now a spastic condition of the legs, with great wasting, though the child can walk a little if helped. She is bright and intelligent, and can easily learn poetry and repeats what is read to her. Dr. Welsh asks whether it would be possible to teach the child to read by the Braille system, and, if so, the best age to begin.

We have referred this question to Dr. J. Lloyd Johnstone, Librarian to the National Institute for the Blind (224, Great Portland Street, W.1), who writes: "There is no reason why the patient should not, at once, commence to learn to educate the sense of touch in the fingers. As she appears to be an intelligent child she should soon be in a position to take up Braille. Children are instructed to read Braille at as early an age as letter-press. At the outset the sense of touch is educated by the use of small beads, and after the child has learned the 'feel' of these under the finger-tips, it is taught the Braille characters in large embossed type. All information as to books and apparatus may be obtained by writing to the Secretary-General, National Institute for the Blind, 224, Great Portland Street, W.1."

BLOOD CHANGES IN T.N.T. POISONING.

"W. B." asks for references to the literature dealing in detail with the symptoms and course of the anaemia caused by trinitrotoluene poisoning during the war. He especially wishes for records of the blood picture, marrow examination, and the subjective symptoms.

The symptoms and signs of poisoning by trinitrotoluene and other substances used in the manufacture of munitions are described in Dr. W. H. Wilcox's Lettsomian lectures on jaundice, 1919, given before the Medical Society of London, and published in full in the BRITISH MEDICAL JOURNAL in 1919. Dr. Wilcox has kindly added the following information: With regard to the blood changes in T.N.T. poisoning, a severe anaemia of pernicious type occurs in some cases, and this may be due to a combination of poisoning by T.N.T., and to bacteriological toxæmia from associated streptococcal infection from the mouth or intestine, the primary cause being the T.N.T. poisoning. The blood changes in T.N.T. poisoning were studied by Captain M. J. Stewart, R.A.M.C., and published in the *Proceedings of the Royal Society of Medicine*, January 23rd, 1917 (Discussion on Toxic Jaundice in Munition Workers), and also in the *Lancet*, January 27th, 1917. The symptoms and signs of cases of progressive anaemia following T.N.T. poisoning are similar to those of pernicious anaemia, and the treatment should be on the lines adopted for such cases.

DILATED PUPILS.

"C. F. R." writes: Miss B., aged 20, is a healthy girl of nervous energetic temperament. About ten years ago the right pupil, for no apparent cause, became widely dilated and has remained so. Two years ago the left pupil followed suit. Both pupils are now widely dilated—the left one being rather the larger. There is very slight reaction to an intensely bright light. There are no other physical signs. No enlarged glands are shown by x rays, and the blood is negative to Wassermann. With suitable glasses she can read for about half an hour, after which eye-strain causes severe headache. She has been seen by three consultants, who can throw no light on the cause or suggest treatment, though two of them—one a neurologist and the other an ophthalmic surgeon—have seen two similar cases, treatment being unsatisfactory. Any treatment would be gratefully accepted by her condition.

INCOME TAX.

"TERRITORIAL" was called up in August, 1914, and served until December, 1918. In the spring of 1917 and 1918 he handed in to the local surveyor of taxes statements of such small amounts as were earned by colleagues on his behalf, and on each occasion was told that he would not be assessed as he was on active service. In July last he was asked to supply particulars of civilian earnings, and has now been called upon to pay £52 4s. tax thereon. He asks whether he has any redress.

Our correspondent seems to have legitimate ground for complaint in being told that he was not taxable and subsequently taxed; but we fear that the question will have to be

settled on the basis as to whether or not the charge is legal. On that ground he appears to have no redress, because such income as might accrue to him as a result of his civil practice is undoubtedly chargeable—on the basis of the amount receivable for each year of assessment. It might, perhaps, be worth while to ask for full particulars of the assessments made (unless they have already been supplied) and to make sure that all proper allowances have been made. We assume that for 1920-21 "Territorial" is assessed at the average amount of his civilian earnings in the years 1917, 1918 and 1919, and not, for instance, on the amount of his earnings for the first post-war year.

"E. A. Y." writes: Last January I bought a large practice (death vacancy) and was afterwards told that I must pay income tax on the three years' average earnings of my (deceased) predecessor. Is this the law, and how am I to find out this average?

"*." That is the law subject to this proviso, that if the successor can prove at the end of the year that the profits have fallen short of the sum assessed through some specific cause, then the average figure can be displaced by the earnings of the year. Such earnings would have to be calculated not on the usual cash basis but on the value of the professional bookings. Our correspondent's only method of arriving at the average would seem to be from an examination of the books of the predecessor, though possibly the local inspector of taxes may have been supplied with some information as to the first two of those three years.

LETTERS, NOTES, ETC.

SURGERY OF THE ELBOW.

MR. R. ATKINSON STONEY, F.R.C.S.I., desires to make two corrections in the report which was sent to us of the discussion on the modern surgery of the elbow in the Surgical Section of the Royal Academy of Medicine in Ireland (January 8th, 1921, p. 48). The official reporter made Mr. Stoney say: "Before the war an ankylosed elbow was looked upon as a success, and excision for it was banned." The correct reading should be, "Before the war excision of the elbow for ankylosis was considered a successful operation, and an ankylosed elbow was considered a surgical failure; but now an ankylosed elbow is looked upon as a success, and excision for it is banned." In the reference, a few lines further down, to primary excision the words "employed by the inexperienced" should be omitted.

IMPROVED MOUTH GAGS.

DR. HARDING H. TONKINS (Ealing) writes with reference to the mouth gag described by Major Black on January 22nd, p. 127: In 1884 I invented a gag upon much the same principle, so far as the non-cutting knife edge tooth plates go. My gag, however, was concave behind the knife edge. It was made for tube-feeding refractory lunatics, and could be introduced behind the molars; and I remember finding it of great value in the case of a man under anaesthesia whose mouth was spasmodically closed so that one could not get at his tongue. With this gag I was able to open his mouth, and, incidentally, to depress his tongue at the same time. The gag was made for me by Messrs. Maw, Son, and Thompson.

ANGIO-NEUROTIC OEDEMA.

DR. A. BERNHARD-SMITH (London, S.W.) writes: Some further account of the case of wandering or angio-neurotic oedema which I published (with a photograph of the patient) in the BRITISH MEDICAL JOURNAL of June 8th, 1901, may be of interest. The father was somewhat gouty, to my knowledge; but neither the patient nor his brother and three sisters have shown signs of gout. There is no history of epilepsy in the family. Some years ago one sister had a single, severe attack of angio-neurotic oedema following dysentery (see a somewhat similar case reported by E. W. G. Masterman, F.R.C.S., BRITISH MEDICAL JOURNAL, April 3rd, 1897); but my patient's oedema, which during 1896-98 was treated with arsenic, iodides and ointments, and special dieting, although no hypodermic injections of serum were given, seems to have worn itself out, as he has not since had a return of the trouble.

TAPEWORM.

DR. J. REID (London, W.C.) writes: Dr. Low's case and treatment in the BRITISH MEDICAL JOURNAL of January 22nd may excuse me for recording an experience. A lad of about 15, a worker on the land, had suffered and been treated without effect for about a year. I gave him a mixture containing 2 drachms of the liquid extract of male fern with an emulsion of castor oil and tragacanth in a 6 oz. bottle, one-twelfth part every four hours. The worm was brought to me, with its head, in a few days. My rationale depended on a desire to keep the worm constantly fed with the filix mas. Filicic acid or isobutyryloxynaphtho-quinone is not to be given with castor oil on account of its poisonous qualities (Squire). Like

dillenic acid, from *Hibbertia volubilis*, which kills the earth-worm after a convulsion, it is insoluble in water and soluble in alkali, hence probably it becomes efficient as a vermicide.

DANGEROUS DRUGS ACT.

MR. A. E. CLEARE, pharmacist of Uckfield, in the course of a letter on this subject expresses the opinion that at the present time anyone can obtain the most dangerous poisons with little or no difficulty, whether for felonious purposes or not. Self-medication, he states, particularly amongst women, is alarmingly on the increase. Not so many years ago the number of drugs which found their way into domestic use were few, and consisted of such harmless things as Pil Rhei Co., Conf. Sennae, Mag. Sulph. But to-day custom has changed. The public seem to have become familiar with the latest drugs, without, of course, understanding their therapeutical properties. I think, he says, the popularity of the tablet has much to do with it; I have found amongst many people a belief that if a drug is in tablet form it must be harmless. When the Dangerous Drugs Act becomes operative, it will not, Mr. Cleare thinks, be effectual in the purpose for which it is intended unless effective measures are introduced to make it so, any more than the Pharmacy Acts of 1868 and other dates have prevented poisonings from taking place. Any law must, to be effective, be provided with the means to carry it out, and therein lies the crux of the whole thing. I do not of course suggest, he continues, that the Pharmaceutical Society is incapable of carrying out whatever new regulations may be made, but the fact remains that in the past regulations with regard to the sale of poisons have been most ineffective. In spite of the regulations being plain and concise—on paper—it has been left, in many ways, to the individual shopkeeper to interpret them according to his individual discretion, and while many—I am glad to think, the majority—have acted conscientiously and well, there are others who practically ignore every restriction that is put upon them, and those the Pharmaceutical Society certainly does not appear to have reached. In general the chemist in small country towns and the back streets of Suburbia is the worst offender, because, knowing his customers personally, he is pretty safe from interference.

THE Food Education Society has issued its report for the past year. A copy of this, together with a list of publications and particulars of lectures and cookery demonstrations, may be obtained for 7d., post free, from the society (Dances Inn House, 265, Strand, W.C.2).

A PLEASANT little adjunct to the treatment of the neurotic child is the "Sleepy Dustman" lamp and night-shade, designed by the wife of a medical man. She tells us it has been of great service in helping to calm the bedtime terrors of nervous children, who cannot bear to be left alone in the dark. It is now made by the Artistic Shade Company, 146, Kensington High Street, W.8, and there is a little story book with verses and appropriate music to reinforce the suggestion of the lamp-shade.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 31, 34, 35, 36, and 37 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 32 and 33.

THE following appointments of certifying factory surgeons are vacant: Bridge of Weir and Kilmacoll (Renfrew), Portadown (Armagh), Strichen (Aberdeen).

A VACANCY is announced for an ophthalmic specialist medical referee under the Workmen's Compensation Act, 1906, for County Court Circuit No. 4, comprising the Bacup and Rawtenstall, Blackburn and Darwen, Blackpool and Fleetwood, Clitheroe, Garstang, Haslingden and Accrington, Kirkham, Preston and Chorley, and Lancaster County Courts. Applications should be addressed to the Private Secretary, Home Office, by February 16th.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 3 0
Each additional line...	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive post-restant letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

133

Bronchial Asthma.

GIUFFRÉ (*Riv. Med.*, November 20th, 1920), at the recent medical congress held in Rome, in opening a discussion on bronchial asthma, dealt chiefly with the pathogenesis of the disease. He believes it is a respiratory neurosis and not an anaphylactic state. He went on to discuss the reflex, anaphylactic, and endocrine theories; with one or other of these three theories most cases of asthma can be explained and the genesis of the various symptoms understood, including bradypnoea, coryza, bradycardia, eosinophilia, hemimerania, etc. Only a few cases can be explained on one hypothesis, usually two, or even all three, of the theories are needed to explain all the symptoms in any given case, and where fever and bronchitis exist this may be due to bacterial infection. However varied the causes and the symptomatology the hyperkinesia and bronchial hyperemia remain the chief fundamental facts. Without a special hyperexcitability of the respiratory neurones one does not get a true asthma. FRIGONI, continuing the discussion, excluded asthma due to some other fundamental disease and pure respiratory neurosis—for example, asthmatic crises in hysteria. Causes may be grouped as disposing and determining. Thyroid or ovarian disturbances, if not directly determining asthma, may favour its development. Tuberculosis and asthma are not as antagonistic as was at one time believed, nor can nasal lesions be accepted as prime causes. Pollen asthma is well established both on clinical and experimental grounds, so also with regard to animal exhalations. About half the cases of asthma still remain to be explained etiologically. None of the alien elements in the sputum (Charcot's crystals, etc.) are pathognomonic although characteristic. Where a specific pollen or protein can be detected vaccine treatment gives excellent results, and adrenalin and pituitrin are sometimes valuable symptomatically.

134

Treatment of Chilblains.

CLAP (*Bull. Soc. de Therap.*, December 8th, 1920) states that during the war he several times relieved the pain caused by this affection in soldiers by applying an elastic bandage either directly over the chilblains or above them. The results were equally good in both cases. Local compression acted more rapidly but was more painful, while the effects of compression at some distance from the chilblains were more lasting. The former method was indicated when there were only a few lesions on the fingers or sides of the feet, while the latter should be reserved for multiple chilblains, chilblains on the toes, and ulcerated chilblains.

135

Epidemic Hiccough at Rheims

RAILLIET (*Bull. et Mem. Soc. Med. des Hop. de Paris*, December 30th, 1920) states that the first cases occurred on November 10th, and that the epidemic reached its height at the beginning of December. About 130 cases had occurred at the time of his communication when the epidemic was beginning to decline. The average duration of the hiccough was from two to four days. In two cases, however, it lasted eight and ten days respectively. In some patients the hiccough persisted throughout the day and night, while in others there were periods of quiet either by day or night. More cases occurred in men than in women. Children were apparently immune. The majority of the cases were not subject to the ordinary form of hiccough, and were vigorous persons without any history of digestive or nervous disturbances. At the time of the attack, however, several patients suffered from mild or severe gastric symptoms. Most of the ordinary sedatives were ineffectual, such as belladonna, chloroform water, camphor, and valerian. Mixtures containing menthol, cocaine, or heroin were sometimes successful, and good results were also obtained by emetics in some cases. Various suggestions have been made as to the cause of the condition, including cold, intoxication by water, bread, ergotin, neuropathy, and a monosymptomatic manifestation of influenza or lethargic encephalitis.

136

Epidemic Encephalitis in Anjou.

DIVICHAL and BLANG (*Bull. et Mem. Soc. Med. des Hop. de Paris*, December 30th, 1920) record their observations on 31 cases of epidemic encephalitis in Anjou, where

50 cases occurred in 1919-20. The predominant feature was motor excitement. Myoclonic movements were the principal manifestation, and were associated with muscular hypertonus. Chorea movements were noted in 5 cases and hiccough in 2; 6 patients showed signs of paralysis agitans, one case simulated generalized epilepsy, and one Jacksonian epilepsy. Ocular symptoms were seen in 22 cases, and consisted in isolated paralysis of the ocular muscles, affection of the iris and ciliary muscle, and in 3 cases paralysis of associated movements. Mental symptoms were found in 14 cases, either in the acute stage in the form of excitement with a dream state delirium and visual hallucinations, or in the late stage. Death occurred in 11 cases, or in 34 per cent. The survivors all showed sequelae, which were as follows: (1) Psychical symptoms in 6 cases, (2) ocular paralysis, (3) paralysis agitans, (4) muscular atrophy.

137.

Small-pox and Tuberculosis

HOWK and LAWSON (*Amer. Rev. of Tuberculosis*, September, 1920) report 7 cases of small pox which occurred in a sanatorium in 1914. All the 7 patients recovered from small pox, and 6 were alive and well in September, 1920. The symptomatology, the appearance of the exanthem, and the duration of the small pox were not influenced by the presence of tuberculosis. In one active advanced case the attack of small pox was followed by a disappearance for four months of sputum and tubercle bacilli, in another advanced case, hitherto progressing rapidly a permanent disappearance of sputum and bacilli took place immediately after the attack of small pox.

138.

Tuberculin Treatment.

ACCORDING to DE BLOEME (*Nederl. Tydschr. v. Geneesl.*, October 2nd, 1920) tuberculin treatment can be most safely employed in cases of pulmonary tuberculosis in which the general condition is good, the pulse is not frequent, there are no complications, there are no tubercle bacilli in the sputum, and there is a tendency to recovery. It is contra-indicated in acute cases or relapses of pulmonary tuberculosis in which the rectal temperature is continuously above 99.8° F. Cases with frequent pulse and nephritis are also unsuitable. De Bloeme recommends tuberculin for localized forms of tuberculosis—for example, of the skin, lymph glands, and especially the eye. As regards tuberculosis in children, he alludes to von Leube's suggestion that all children of tuberculous parents who give a positive von Pirquet reaction should be given tuberculin.

139 Consecutive Bilateral Artificial Pneumothorax.

FEELDMANN (*Tuberculosis*, August, 1920) reports the case of a woman, aged 31, first seen in July, 1916, when she showed signs of phthisis, chiefly in the right lung (diminished expansion, slight dullness at the apex, crepitations; on the left side harsh breathing at the apex, but no adventitious sounds). The radiograms showed opacity of the middle lobe on the right side, and some opacity of the left apex. The symptoms dated back four years. Artificial pneumothorax was induced on the right side, the signs and symptoms improved very much. The lung collapsed in about three weeks. In January, 1917, a few rales were detected at the left apex, and as the right side was so much better, treatment on that side was stopped, after six weeks the lung resumed its original volume, and the radiograph showed evidence of sclerosis in the previously diseased area. About the end of February pneumothorax was induced on the left side with excellent results, so that at the beginning of March, 1918, no further treatment was necessary. The patient has remained well so far.

140. Contraindications to Dental Extraction in Cardiopaths

CALPI (*Riv. Med.*, September 4th, 1920) draws attention to the danger of septic poisoning from dental extraction and the possibility of the germs spreading to the myocardium and so weakening an already damaged heart. He quotes two cases (one fatal) where after extraction of a tooth fever and septicaemia set in. He suggests that where cardiac compensation is not very sound it is better to drain the dental abscess rather than proceed to extraction, which exposes more of the septic alveolus. Later on, when as a result of drainage the region of the tooth is less septic, it can be extracted.

141. Bilateral Peripheral Facial Paralysis.

ASKGAARD (*Hospitalstidende*, September 8th, 1920) discusses de Castro's thesis, published in 1919, in which he calculated that 95 per cent. of all cases of bilateral peripheral facial paralysis are due to syphilis. The author's material is not great enough to refute this indictment, but he records a case in which syphilis could be definitely excluded. The patient was a man, aged 35, who denied having contracted syphilis, and who gave a negative Wassermann reaction. He had been perfectly well till he contracted severe bronchitis, for which he had to go to bed. During this illness, first the left, and two days later the right facial nerve became paralysed. There were no giddiness, headache, loss of consciousness, diplopia, nor convulsions, and the electrical reaction of degeneration could not be elicited. Within ten days of coming to hospital the right side of the face had become almost normal, but there was still evidence of paralysis on the left side. This case is regarded by the author as "rheumatic" — a term which he admits is a confession of ignorance. The bronchitis was probably a predisposing factor. In another of the author's cases the development of bilateral facial paralysis coincided with a secondary eruption of syphilis, with which the author correlated the paralysis without question. Though he does not specifically reject de Castro's estimate of the part played by syphilis in bilateral facial paralysis, the author maintains that in most cases of unilateral peripheral facial paralysis the cause is rheumatism.

142. Adrenalin in Erythromelalgia.

CHATELLIER (*Ann. de Derm. et de Syph.*, 1920, No. 5) records the case of a neuropathic woman, aged 23, suffering from violent attacks of erythromelalgia which were not affected by ordinary analgesics, such as aspirin, pyramidon, and morphine, but were rapidly cured by a subcutaneous injection of $\frac{1}{2}$ mg. of adrenalin.

SURGERY.**143. Benign Intestinal Tumours.**

VAN LIER (*Nederl. Tijdschr. v. Geneesk.*, November 27th, 1920) states that the diagnosis of intestinal tumour is too frequently regarded as a sentence of death, the possibility of a benign growth not being taken into consideration. Statistics, however, show that 20 per cent. of all pyloric tumours are benign. In the course of the last six months van Lier has seen three cases of advanced pyloric stenosis in elderly persons due to benign tumours and cured by gastro-enterostomy. Benign tumours of the ileum practically never occur, the growths in this part of the intestine being usually sarcomata. The colon from the caecum to the anus may present inflammatory swellings, of which perisigmoiditis is the most frequent. Van Lier records a case of stricture of the sigmoid to show the falsity of the old doctrine that all strictures of the large intestine are due to syphilis or tuberculosis. The Wassermann reaction was negative, and the *post-mortem* examination showed the absence of any malignant growth. Cohnheim (1913) also states that non-specific colitis and proctitis may give rise to stenosis.

144. Luxations of the Thumb.

GUIBÉ (*Rev. d'Orthopéd.*, 1920, 7) discusses at great length the dislocations and subluxations of the terminal phalanx of the thumb. A very clear account is given of the anatomy and workings of the interphalangeal joint. Backward dislocation is of course the common displacement, and whilst a large number of these injuries are reduced at once by the patient himself or his friends a certain number there are in which the phalanx remains out of position. Guibé clearly shows the mechanism of these unreduced cases by x-ray photographs of experimental luxations on autopsy material. There is never any difficulty in reducing the dislocation. An open operation is indicated, a flap being turned down on the dorsal aspect and the long flexor tendon carefully preserved. Dislocation of the long flexor tendon forwards is very uncommon, and lateral terminal phalanx forwards is very uncommon, and lateral luxation still rarer. The number of forward dislocations reported is scarcely more than six, so that those who have seen examples of this displacement should record them without delay.

145. Syphilitic Polyneuritis.

ACCORDING TO KERL (*Wien. klin. Woch.*, October 14th, 1920), who records a personal case, the occurrence of syphilitic polyneuritis, which was first described by Ehrmann in

1886, is a rare event, only 11 cases having been collected by Steinert in 1909, and 20 by Demanche and Menard in 1911. In most of the cases the polyneuritis appeared after the syphilitic eruption, and there are only four cases on record in which it developed before or at the same time as the rash. Kerl's patient was a woman aged 45, who suddenly developed peripheral paralysis of the right upper and lower extremity and of the right facial nerve in all its branches. Two days later a generalized maculo-papular eruption appeared, together with a sore throat. The Wassermann reaction was positive in the blood though negative in the spinal fluid. Mercurial neuritis could be excluded, as the patient had not had any previous treatment and was not engaged in any trade in which mercury was employed. Other causes, such as alcohol and rheumatism, could also be excluded. The syphilitic nature of the polyneuritis was confirmed by the rapid recovery following antisyphilitic treatment.

146. Volkmann's Contracture.

IN opening a discussion at the French Orthopaedic Congress, DENUCE (*Gaz. hebdomadaire des Sci. Méd.*, November 7th, 1920) said that Volkmann's contracture, attributed by Volkmann to myogenous causes connected with ischaemia, had been ascribed, in part at least, by Bardenheuer and Hildebrand to nervous affection. During the war it had been found that Volkmann's contracture occurred in adults as well as in children; in the lower as well as the upper limbs; with or without preceding fracture or application of splints. Nervous lesions coexisting with Volkmann's contracture might (1) be due to the contracture; (2) be associated with it, both being due to some third cause; (3) cause the contracture. Denucé believes that while ischaemia may be the cause of flaccid palsies, paralyzes with contracture (and especially those associated with much fibrosis) are due, in some degree, to interference with sympathetic nerves. According to Morat and others muscle tonus is regulated by a reflex, of which the afferent and efferent paths are situated in both the spinal and sympathetic nerves. These sympathetic fibres are to be found both in the spinal nerve trunks and in the perivascular nervous plexuses. Too tight application of a splint, by interfering with vascular expansion, might lead to functional troubles of the sympathetic. Leriche, in his work on periarterial sympathectomy, has shown that for contraction of voluntary muscle there is necessary, besides integrity of the muscle and of the motor nerve, integrity of the perivascular sympathetic filaments. From an examination of cases Denucé found that in the majority of instances there had been fracture, with irritation of nerve or arterial trunks by the displaced bony segments or by splinters. For treatment he advocated tenoplasty operations (associated if necessary with neurolysis) or, in the cases associated with extensive fibrosis, the sympathectomy of Leriche.

147. Dissecting Abscess of the Caecal Wall.

HAGLER (*Surg., Gyn., and Obstet.*, November, 1920) records the case of a young male in whom acute appendicitis was diagnosed. Operation was performed within twenty-four hours; the appendix was slightly injected, but the caecum was greatly enlarged and fluctuant. The swelling was found to be due to a collection of pus between the circular muscle layer and the submucosa; there was no evidence of gangrene or perforation. The post-operative course was regular.

148. Colloidal Gold in Septicaemia.

LAY (*La Clinica Chirurgica*, March-April, 1920) employed intravenous injections of colloidal gold in 9 cases of septicæmia. In 5 cases the results were excellent, the first being due to the typhoid bacillus, the second to the paratyphoid B bacillus, the third to *Staphylococcus albus* and streptococcus, and the fourth to *Staphylococcus aureus*, while in the fifth case, which was that of a wound of the arm due to an explosive bullet, no bacteriological examination was made. After each injection there was intense shivering and rise of temperature, followed by a rapid fall, accompanied by profuse sweating and a sense of comfort. The wounds became clear after the first or second injection. No cases of intolerance were observed.

149. Herpes Ophthalmicus.

ROELOFS (*Nederl. Tijdschr. v. Geneesk.*, December 25th, 1920) records the case of a girl, aged 12, who, three days after getting some soda in the right eye, developed right ophthalmic zoster, and about a fortnight later external and internal ophthalmoplegia of the right eye, an affection of the cornea closely resembling the keratitis punctata superficialis of Fuchs, and slight atrophy of the iris, the

result of inflammation. The Wassermann reaction was negative in the blood and cerebro spinal fluid. A pleocytosis of 30 was found in the cerebro spinal fluid. Improvement took place, but fourteen months after the onset the right pupil was still sluggish and irregular in shape, and accommodation was difficult with the right eye.

150. Operation for Detached Retina.

CHAPMAN (*Canadian Med. Assoc. Journ.*, November, 1920) records two cases of detachment of the retina treated, according to the method of Thomson and Curtin, by trephining the sclera (after raising the conjunctival flap) and repeated aspirations. The first case was one of extensive detachment in a man aged 47; six weeks after the trephining there was no dimness of vision in any area, and central vision was 36.

151 Intermittent Intestinal Obstruction caused by Murphy's Button

NEUBERGER (*Wien. Klin. Woch.*, November 4th, 1920) reviews the literature, and records the following case. A man had a portion of the large intestine resected for a tumour in August, 1906, anastomosis being made with a Murphy's button. The patient made a good recovery, and it was not until August, 1919, that he began to suffer from intermittent attacks of intestinal obstruction of increasing severity. As the x rays showed the presence of a Murphy's button in the left hypogastric region, laparotomy was performed thirteen and a half years after the first operation, and the button was found in a diverticulum of the transverse colon projecting into the lumen of the gut. After its removal complete recovery took place. Kellogg's case, in which a Murphy's button was removed fifteen and a half years after the operation, is the only instance of a longer stay of this foreign body in the intestine.

OBSTETRICS AND GYNAECOLOGY.

152 Intestinal Obstruction and Peritonitis in Pregnancy, Labour, and the Puerperium.

ACCORDING to KÖHLER (*Wien. Klin. Woch.*, October 21st 1920), intestinal obstruction is a rare complication of pregnancy, labour, and the puerperium, less than a hundred cases having been recorded. Apart from peritonitis of appendicular origin, which is not uncommon, diffuse peritonitis in pregnancy is still rare. Köhler records two cases of peritonitis and four of intestinal obstruction complicating pregnancy and the early or late stage of the puerperium, all of which were fatal. There does not appear to be any definite connexion between the number of confinements and intestinal obstruction. The age of the patient has also no importance, and it was a mere coincidence that three of Köhler's cases were in the fourth decade. On the other hand, the early stage of the puerperium is a predisposing factor, as the majority of cases have occurred between the second and ninth day after delivery. In most cases the association of intestinal obstruction and peritonitis with pregnancy, labour, and the puerperium is merely accidental, intestinal obstruction usually being due to the same causes as in the non-pregnant state, and in only a few instances to the enlarged uterus alone. The association has an unfavourable prognosis. As regards treatment, delivery by vaginal section is best. Operation is indicated in apparently hopeless cases, if only to save the life of the child. It is remarkable that even in diffuse peritonitis during pregnancy injection of organic extracts such as enteroglandol, though having no effect on the paralysed intestinal muscles, acts powerfully on the uterine muscles, and enables a child to be born.

153 Glycosuria in Pregnancy.

ANDERODIS and DUBREUIL (*Gaz. hebdomadaire des Sci. Méd. de Bordeaux*, January 2nd, 1921) state that the association of glycosuria and pregnancy may take place under two different conditions—namely, (1) a woman who has been previously diabetic may become pregnant, (2) a hitherto healthy woman may develop glycosuria in the course of one or several successive pregnancies. Both of these occurrences are rare, the writers having seen only two examples during the last twenty years. In the first case a diabetic woman, whose urine contained 20 to 40 grams of sugar per litre of urine, gave birth to a full term macerated foetus weighing 7 kilos, which had died in utero eight days before birth. In the second case the woman had had glycosuria during her last two pregnancies

but had shown no other signs of diabetes, and the urine, apart from pregnancy, had been normal. Examination of the urine before the birth of her fourth child showed an amount of sugar ranging from 50.75 grams and 52 grams per litre. A stillborn child, weighing 5½ kilos, was born at the end of the eighth month. Examination of its pancreas showed enormous enlargement of the islands of Langerhans, the function of which is to control the sugar content of the blood.

154 Detachment of the Placenta by Gabaston's Method.

As early as 1826 an Italian, Benedetto Mojon, described a method of detaching the placenta by the injection of cold water into the umbilical vein. This method fell into abeyance, and was rediscovered in 1914 by Gabaston of Buenos Aires. Between April, 1916, and March, 1920, W. GEJROT (*Hygica*, October 16th, 1920) has tested this method in the Communal Maternity Hospital in Stockholm. The fluid injected was sterile water cooled to a temperature of 12 to 15°C. The quantities injected ranged from 300 to 600 c cm. The method was adopted only when there was considerable delay in the spontaneous expulsion of the placenta, so that it could be tested only in 14 out of almost 3,000 births. In 7 cases there was only retention of the placenta; in the remaining 7 haemorrhage, as well as retention, was the indication for this treatment. In one of the 7 cases in the first class the injection failed of its object owing to pathological changes in the placenta. In 5 cases detachment of the placenta was successfully effected, and in one manual detachment was necessary, probably because the patient was too debilitated by illness to react to the stimulus of the injection. Of the 7 cases of haemorrhage, 4 reacted satisfactorily to the injection by detachment of the placenta. In the remaining 3 this device proved futile. In all the successful cases the injection was almost immediately followed by powerful labour pains. The author considers that the distension of the placenta by the fluid is the main factor determining the success of this treatment, but it is probable that the coldness of the injected fluid also helps to promote contractions of the uterus.

155 Hydatidiform Mole in association with Ovarian Cysts

DAVIS (*Gynec. et Obstet.*, 1920, ii, 1) records the case of a 2 para, aged 24, who suffered during the third month of pregnancy from slight haemorrhage, albuminuria, vomiting, and tachycardia, the size of the uterus increased with undue rapidity. After induction of cervical dilatation a hydatidiform mole weighing 1 kilogram was removed digitally. Uterine involution took a normal course, but one month later the abdomen was opened for torsion of an ovarian cyst, and subtotal hysterectomy was performed. There were large cysts of both ovaries, and a cancerous condition was present in one part in the uterine mucosa. JEMTEL (*Gynec. et Obstet. et L'Annee med. de Caen*, June, 1920) has operated on two patients for hydatidiform mole associated with large bilateral ovarian cysts. In the first patient an unduly enlarged uterus, afterwards proved to contain a hydatidiform mole, was removed at the same time as the ovaries. In the second case, that of a woman aged 26, whose last confinement had occurred six months previously, expulsion of a hydatidiform mole was followed by persistence of uterine and adnexal enlargement and of haemorrhage.

156 Pyelonephritis following Pregnancy Cured by Intravenous Injections of Urotropine

CARLES, CREYX, and FRANÇOIS (*Gaz. hebdomadaire des Sci. Méd. de Bordeaux*, January 2nd, 1921) report the case of a woman, aged 30, who as the result of a difficult labour contracted a vesical infection, and three weeks after delivery developed pyelonephritis with signs of severe infection, typhoid state, high temperature, rapid pulse, intense haematuria, and pyuria. Intravenous injections of urotropine were given daily, and later every two days, in doses of 2 to 10 c cm. of a solution containing 0.10 g. of urotropine per cubic centimetre of distilled water. In five days' time the temperature fell, the urine became clear, and complete recovery took place.

157 Viability of Spermatozoa.

NEUBERGER (*Vonatschr. f. Geburts u. Gynäk.*, July 5th, 1920) was able to demonstrate the presence of living spermatozoa in normal Fallopian tubes in the case of two patients who underwent laparotomy fourteen and fifteen days respectively after the last possible date of sexual intercourse.

PATHOLOGY.

158. Diabetes and Infections.

CASTRONUOVO (*Rif. Med.*, October 9th, 1920) holds that in considering the etiology of diabetes we ought to pay more attention to the immediate and late effects of infectious diseases, especially malaria, tuberculosis, and syphilis. Unsuitable diet in relation to climate should also be borne in mind, as it may induce changes in the digestive organs and lessen the power of the defensive organs to deal with infective poisons. In this respect the liver and pancreas are chiefly at fault. The tuberculosis which is often seen in diabetics should be looked upon as a precedent condition, although latent, rather than an effect of the diabetes; hence the importance of careful search for latent malaria, tuberculosis, or syphilis, and of treatment of these as a preventive of diabetes.

159. A Rapid Sero-diagnostic Method in Tuberculosis.

GOLDENBERG and FRIED (*C. R. Soc. Biologie*, November 6th, 1920), who previously reported 94 per cent. of positive results in 150 cases of pulmonary tuberculosis, have tried more recently a more rapid method, which consists in employing the unheated serums as the source of complement. Seeing that unheated human serum is very variable in its effect on sheep corpuscles, it was necessary to find out for each serum its haemolytic index in order to be sure that it was neither too great nor too feeble. A human serum that in doses of 0.1 c.cm. to 0.2 c.cm. can dissolve 0.6 c.cm. of a 5 per cent. suspension of sheep corpuscles serves very well for the rapid reaction. The authors put 0.1 c.cm. of the serum to be examined into each of three haemolysis tubes and add increasing doses of Besredka's antigen—namely, 0.1 c.cm. in the first, 0.2 c.cm. in the second, and 0.3 c.cm. in the third. After the tubes have been incubated for an hour the suspension of sheep corpuscles is added in doses of 0.3 c.cm., 0.2 c.cm., and 0.1 c.cm. respectively. After half an hour's incubation the results are read. The human serums should be examined within twenty-four to thirty-six hours after bleeding, because after that they lose a great part of their complement. Of 153 serums from cases of pulmonary tuberculosis, 8 were rejected because they were either too haemolytic or had practically no haemolytic effect. Of the remaining 145 serums, 137 gave a positive fixation (93.75 per cent.), and 8 gave a negative result. In all these negative cases the patients died within a few weeks of the test. In cases of surgical tuberculosis 100 per cent. positive results were obtained. In 19 serums from diseases other than tuberculosis the results were always negative. The authors consider that the rapid method gives as good results as the slower complement deviation method. In making their comparison they used the same serums for both methods.

160. Haematogenous Renal Infection.

PEDROLI (*La Clinica Chirurgica*, March-April, 1920) records 15 cases of haematogenous renal infection, of which he considers the staphylococcus to be the most frequent causal organism. He attaches considerable importance to factors which cause an obstruction to the flow of urine, such as pregnancy, movable kidney, and calculus. The most frequent macroscopical lesions are the diffuse nodular form and a focal form. The course of the disease is sub-acute. The best treatment is nephrotomy and nephrectomy, after which the prognosis is favourable.

161. Histological Changes Produced by Salvarsan.

KOLMER and LUCKE (*Arch. of Derm. and Syph.*, September, 1920), as the result of their experiments on animals with single and repeated injections of salvarsan preparations, state that the changes produced in the tissues by products of the neo-salvarsan order are of the same character as, though of a much less severe degree than, those produced by salvarsan. Acid or non-neutralized solutions of the latter caused in all organs severe vascular injuries characterized by congestion, haemorrhagic extravasations, and thrombi. Single large doses of both drugs produced similar but less marked changes, but areas of focal necrosis and cellular degenerations in heart muscle, liver, and spleen were rather prominent; the kidney lesions consisted of these changes as well as varying degrees of tubular necrosis, and the suprarenals showed in addition well-marked changes in the lipoid and chromaffin contents. When multiple small doses of the drugs were given, similar vascular, renal, and suprarenal lesions resulted, and focal areas of cellular degenerations and necroses were frequently well

marked in the heart and liver. The maximum change were produced by large doses of acid solutions much greater than those which would be employed in treatment but multiple injections of therapeutic doses were not without definite effects.

162. Familial Tabes.

BURROW (*Journ. of Neurology and Psychopathology*, November, 1920) records the medical history of 11 surviving members in a family of eight, born of healthy parents; four have acquired syphilis from different sources, with resulting tabes dorsalis. A fifth acquired gonorrhoea and possibly syphilis; it is probable that he now suffers from early tabes. A sixth escaped venereal infection and remains healthy. It is suggested, in the light of the above record, that tabes dorsalis cannot be attributed to a special strain of spirochaete acting on tissues specially sensitized, either by natural familial peculiarity, or by certain methods of treatment.

163. Diagnosis of Bubonic Plague.

VIOLLE (*C. R. Soc. Biologie*, October 16th, 1920) says that though the investigation is easy when the bubo is recent yet with old lesions the indirect method of demonstrating the infection, by agglutination, precipitation, or complement deviation, is very uncertain. He states that not only is the bubo the focus for the development of the plague bacillus, but it is also the site of the presence of the antibodies, which only later gain the general circulation. The reaction phenomena would thus seem to be primarily local. He finds that positive agglutination reactions may be obtained with the liquid extract of the bubo. The method is easy to follow; it is the ordinary serum agglutination method, but in this case the serum is replaced by the bubonic pus. The reaction is positive with the pus from lesions several days or even several weeks old; it is negative with the juice of recent buboes. It is never obtained with the pus of cases of adenitis due to other organisms.

164. Protein Sensitization in Eczema.

RAMIREZ (*Arch. of Derm. and Syph.*, September, 1920) calls attention to the clinical applicability of protein sensitization to the investigation of eczema. As our present knowledge of the etiology and specific treatment of eczema is so vague, any method that will give us a clearer understanding of the condition is worthy of note. Various American observers during the last few years have laid stress on the relation of anaphylaxis to eczema, and have maintained that the majority of cases of chronic eczema are due to food sensitization. It is obvious that the more extensive the list of food proteins used in the skin scarification tests the higher will be the percentages of positive reactions. Ramirez tested 78 cases of eczema with food proteins and obtained 30 positive skin reactions, the greater majority of these being produced by more than one protein. He is of opinion that only a small percentage of all eczema cases are anaphylactic; when the eczema is associated with asthma or hay fever it is usually anaphylactic, and true anaphylactic eczema occurs more frequently under the age of 30. The treatment consists solely in the removal from the diet of the particular proteins giving the positive reaction.

165. Central Neurofibromatosis.

CHRISTIN and NAVILLE (*Ann. de Méd.*, July, 1920), who record five personal cases, state that in sixteen cases of central neurofibromatosis where information was available the onset was always before the twentieth year. As regards the duration of the disease, one should bear in mind the great length of the latent period or stages of arrest which may follow the first symptoms. Of 18 cases 11 lasted less than four years, 3 from five to ten years, one terminated after twenty-three years, and one after twenty-seven years. The prognosis is very bad, as out of 14 cases 8 died before 20, 2 between 21 and 30, 2 between 31 and 40, and 2 between 41 and 50. Bilateral central deafness was noted in 16 out of 23 cases, in 4 there was unilateral deafness, in 3 no definite information was available. Vestibular symptoms are very frequent, but are not so pronounced clinically. In spite of the size and extraordinary number of the endocranial tumours present in such cases there is a frequent absence of intense cerebral disturbance or of torpor and somnolence. All other cranial or spinal nerves may be affected. In less than two-fifths of the cases cutaneous neurofibromatosis were associated with endocranial lesions. A familial or hereditary character was found in several of the cases.

The Cameron Lecture

ON

THE NECESSITY OF ORTHOPAEDIC TRAINING:

ITS RELATION TO THE PREVENTION AND CURE OF DEFORMITIES.

DELIVERED AT THE UNIVERSITY OF EDINBURGH ON JANUARY 14TH, 1921.

BY

SIR ROBERT JONES, K.B.E., C.B., M.Ch.,

F.R.C.S. (ENG.), IREL., AND EDEN.

LECTURER ON ORTHOPAEDIC SURGERY, LIVERPOOL UNIVERSITY;
DIRECTOR OF ORTHOPAEDICS, ST. THOMAS'S HOSPITAL, LONDON.

ONE of the greatest of all honours that a surgeon can receive is the Cameron prize from the University of Edinburgh. It is needless to say how deeply grateful I am to have been selected by your university, and when I think of the distinguished men from various countries who have been recipients in years gone by, I am only too painfully conscious of my unworthiness. Were it not for the tragic incidence of war and the opportunity given me to organize schemes of physical reconstruction the prize must needs have fallen into better hands. It is because it bears relation in this instance to war work that I venture to give you a very simple address relating to the cripple problem generally, both infant and adult, pointing out some of the lessons which the war has taught us—more especially in relation to segregation and the prevention of deformity, emphasizing the necessity of paying more attention to the education of students in orthopaedic principles if they are to be efficiently equipped in after-life. The prevention of surgical tragedies is largely dependent upon the general practitioner, and his usefulness is largely dependent upon his academic training. He frequently sees the beginning of diseases when he enters practice—a phase of work which he has hitherto only studied theoretically—for his hospital experiences have been largely concerned with more advanced stages. He fills an extremely responsible position in most departments of his work, and this is especially true in regard to the early advent of deformities. These deformities are mainly associated with tuberculosis, rickets, and infantile paralysis, but then there are others of congenital origin.

It is evident that many of the deformities due to these conditions may be altogether prevented, and that practically all of them may be so corrected as to enable the patient to become ultimately a valuable industrial asset. An uncorrected deformity may often be the result of parental obstinacy, but not infrequently it is due to a want of knowledge on the part of the practitioner. We have only to visit any out-patient department to be satisfied as to the prevalence of the uncorrected cripple—often the untreated cripple. They are seen in every corner of the earth. If we inquire into the causes of these failures, we find that many of them were not seen in the early stages; many were refused hospital accommodation; others admitted into wards had to be evacuated early because of the pressure on beds; others suffered because there had been lack of continuity of treatment; most of them had not been supervised by surgeons sufficiently interested in that type of work. It is evident, if we are to prevent deformity, we must teach the fundamental principles in such a way that the teaching will bear fruit in remote places. We must reach the practitioner because we have to trust to him for an early diagnosis, and he should at least know the possibilities of modern treatment. The most effective way to accomplish this is through the mind of the student.

To illustrate the value of early corrective treatment we will consider for a few moments a simple type from each of the four groups from which deformities are derived. From the congenital group we will select an ordinary case of congenital equino-varus.

Congenital Deformities.

It is quite common in England to see these cases left for many months without any treatment of a systematic kind. Indeed, some surgeons of repute speak of postponing treatment until the child can walk. They do not

realize the irregular growth that takes place in the tarsus blocking and fixing the foot with increasing effect. It is quite true that a club-foot requires the final act of walking to complete its recovery, but the deformity itself can be completely eradicated in days or weeks, and by methods which can be easily taught to the practitioner in charge if the attempt is made *sufficiently early*. Every one should be taught that the earlier treatment is started, the better the functional result. How often we hear of "recurrences"; that they take place is constantly affirmed by writers as if they were enunciating a principle. Here, again, it should be insisted that a cured club-foot (an over-corrected club-foot is not necessarily a cured one) cannot recur—an over-corrected one frequently does. It is futile to correct obstructive and skeletal elements if the other factors are ignored. One of the causes of these so-called "recurrences" is weakened overstretched dorsiflexors and peronei. Until the child can over-correct its own deformity by a voluntary act, the foot is subject to the same influences that bring about foot-drop in infantile paralysis. If you examine many so-called "cured" club-feet, you will note the weakened condition of these muscles; if simple methods of treatment were applied for rectifying the deformity and restoring the function of the foot, there would be no need for cumbersome antiquated instruments reaching to the pelvis to keep a foot from turning in. Such implements suggest a serious misunderstanding of fundamental principles.

Rickets Deformities.

Take another group of deformities—those associated with rickets. The etiology of this condition is sufficiently known to merit some organized method of control. Recent investigations with regard to vitamins have served to confirm us in our view that it is largely a dietetic disease intensified by insanitary conditions. It is the practitioner who, here again, appears first upon the scene. He knows that mother's milk is better than the pernicious substitutes, and he knows the benefit of fresh air and the evils of overcrowding. If he preached this doctrine with enthusiasm, considerable headway would result in the prevention of rickets. When the disease appears he should know of the danger to soft bones of crawling and walking; he should realize the direct harm done to the child by the way the mother carries it; and, later, when deformity has become evident, how dangerous it is to tell the parents that "the child will grow out of it." When the bones are soft, the recumbent position, a frame and a bandage, without any drastic surgical methods, will correct the worst deformities in the young, and the bones will harden in their correct alignment provided feeding is suitable and the child is kept in the open air and not allowed to walk until the bones are firm.

Then we surgeons are often to blame when the rachitic come to us with their deformities. It is the osteotome, the saw, or osteoclast which we rely upon to straighten the limb, but how rarely do we take adequate protection against recurrence! Our out-patient departments abound with cases in which deformity has been corrected, and has recurred worse than ever, because of deficient after-care. This very properly brings our surgical methods into disrepute. For here again we have not merely to correct the deformity, but to cure the disease—not merely to straighten the soft bones, but to harden them. Deformities of the extremities should never be allowed to occur in rickets, and to fail to rectify them if they appear is a reproach either to the parents, to the surgeons, or to both. If the deformity, having been corrected, returns, it is a serious reflection upon someone.

Deformities due to Tuberculosis.

Again, let us refer to tuberculosis in children. We should be able, given reasonable State facilities, to eradicate this dreadful evil from our midst. If it does appear we should be able to prevent any deformity due to faulty alignment. Most practical and suggestive work on the etiology of tubercle in children, as you know, emanated from Edinburgh under the direction of Sir Harold Stiles, assisted by Mr. Fraser and Mr. Mitchell, who, with scientific methods and infinite labour, traced the infections from cows to children, and were able to correlate their clinical and pathological findings. No less than 60 per cent. of bone and joint disease were due to bovine infection. They found that 37 per cent. were due to the human bacillus, and in 62 per cent. of the human type a history of pulmonary

trouble existed in a parent whereby direct infection could take place. These experiments should be repeated on a large scale all over the country. Even now, at a minimum computation, one specimen of mixed milk in every ten contains living tubercle bacilli. Stenhouse Williams, an acknowledged authority, states that about 30 per cent. of the cattle in this country are affected with tubercle, and that of the total cattle only 2 per cent. will be in such an advanced stage of disease as to be affected by the Tuberculosis Order. "What," he pertinently asks, "is to become of the remaining 28 per cent.?"

What good can result by promulgating theories as to the immunizing of the race by feeding our children on living tubercle bacilli when we see the havoc and tragedy around us? It discourages any preventive effort which the State may make, and supplies the careless dairyman with an argument of immeasurable evil. Is it too much to insist that our milk should be so purified that no living tubercle bacillus should be allowed to enter the mouth of a child? The practitioner here again has a great gospel to preach. If in spite of all a joint becomes involved it will come under his observation first. Again, I have only to refer to the deformities of tuberculous joints, and to insist that a knowledge of the beginnings, and of the sequence of events, would relieve our hospital beds of much pressure and the child of much suffering.

Deformities after Acute Anterior Poliomyelitis.

We do not know enough of infantile paralysis, in spite of the investigations that have recently been made by Flexner, Clark, Osgood, and Lovett, but we have sufficient knowledge to treat it as a dangerously infective disease which should involve placing the family in quarantine, and guarding the healthy children as strictly as they would be guarded against any other acutely infectious disease. The early treatment of infantile paralysis, again, is in the hands of the family doctor. The surgeon very rarely sees the case in the acute stage, and then only when pain occurs or paralysis is discovered. Treatment should be undertaken at once, and should consist of complete rest of the nerves and muscles. I should make it a rule in every case, whether pain is present or not, to keep head and spine at rest just as if we were treating an inflamed area. During both the acute and early convalescent stage the treatment should be protective, and this term should include the prevention of postural errors such as tend to give an initial bias towards deformity. The rapid recovery of muscular groups in extensive paralysis suggests a pressure upon nerve cells which, under given conditions, is rapidly dispersed. Complete destruction of nerve cells is comparatively rare—hence the very late recoveries which often follow treatment. The family doctor may materially shorten and limit the disease, and prevent infection by early rest and isolation, while the risk of the advent of deformity and functional disability can be materially lessened by recognizing as a principle that the paralysed muscle should not be allowed to stretch.

Orthopaedics in the War.

Nearly all the crippling deformities of children and adults are included in the branch of surgery which, for the want of a better name, we call "orthopaedic," and the upper and lower extremities present its main field of activity. This type of surgery formed a large proportion of the injuries of war, and it will readily be admitted that many early failures would have been avoided if British university and hospital training all over the country had embraced in the curriculum the practical teaching of orthopaedic surgery.

Frequent visits round our Command Dépôts revealed the shortcomings of the routine teaching, for one found segregated every type of deformity; most of it need never have occurred had sufficient time been spent in educating the student in the principles which govern the development of deformity. These revelations implicated not merely auxiliary hospitals, but the best known hospitals in the land. The cases we met with were malunited and ununited fractures, stiff and ankylosed joints, injuries of peripheral nerves, partial destruction of the spinal cord, faulty fixation of joints, deformities due to the contraction of scars, and malposition due to functional causes. We found ankylosed joints being massaged, the limb often fixed in the position of least functional usefulness. We found old arthritic joints being

moved with calamitous results, simple adhesions treated as if inflammatory activity were present, the after-effect of peripheral nerve injuries treated without regard to stretching of paralysed muscles; frequently cases in which nerves had been sutured arrived at the camp without a protection for the disabled muscle, and many cases had been allowed to contract so as to deprive joints and fingers of all usefulness. These tragedies did not necessarily originate in Command Dépôts, but often arrived there when the mischief had been done. They were not necessarily due to ignorance or neglect; often they were the result of scarcity of beds, early evacuation, want of continuity of treatment, but the conclusion was also forced upon one that they displayed a lack of orthopaedic training on the part of surgeons and practitioners generally. The Command Dépôts in point of fact presented large groups of cases where Nature unassisted had been allowed to do its curative work without regard to restoration of function. The orthopaedic mind is taught to think in terms of function. It has mainly to deal with a pre-operative and a post-operative stage. The operative stage, although often essential, has only a proportionate value. Orthopaedic operations are usually measures preliminary to the re-education of muscle and restoration of function. They include the maintenance of joints at limbs in proper position in order that injured tissue may recover functional efficiency. The period of disability materially shortened if the limb is protected against deformity while the wound is being allowed to heal. We may be certain that gross malunion of a fracture is not only deplorable but preventable. Most of the malunited fractures of the war were due to the inefficient fixation of the limb in the presence of sepsis or to inexperience of the surgeon in regard to completion of consolidation. Later in the war, the soft tissues were allowed to heal with the bone in good alignment, and this position was maintained while body pressure was permitted. Attention to these two points resulted in a marked decrease of deformity, and, in consequence, an improvement of function. Even yet surgeons do not fully realize that a fracture of the femur which has recovered sufficiently to be unyielding to manipulation may yield to the incidence of body weight. Pain on pressure over the site of fracture suggests an unsound or delayed union. Pain on pressure and an excessive callus display, requires special protection in order that yielding may be avoided.

The deforming contraction of scars which we found in Command Dépôts could be avoided by recognizing certain principles. The wound should be allowed to heal with the limb placed in a position opposed to the contractile force and the surgeon should remember that the bigger the mass of granulation, the more massive and contractile the organized fibrous tissue proves. Wounds in the axilla should be allowed to heal with the arm abducted; in the flexure of the elbow, with the forearm extended; of the wrist and palm, with the joint dorsiflexed, and so on with the other joints. Fully matured fibrous tissue has no more tendency to contract than any other tissue; as a scar takes a long time to be composed of fully matured tissue, the precautions taken against contractures must be prolonged.

It was in consequence of this ever-increasing stream of deformity that the Orthopaedic Centres were started, where the principle of segregating special groups of cases came to be recognized as paramount. From all parts of the country cases poured in. We started with 250 beds in Liverpool, and rapidly extended into the principal towns of Great Britain and Ireland until our beds eventually numbered over 20,000. The staffs were made up of general surgeons, orthopaedic surgeons, neurologists, and chiefs of special departments. We were permitted to keep our cases longer than in the general military hospitals, and were given every modern facility in the way of equipment. For psychological and reconstructive purposes we introduced the curative workshops. These Orthopaedic Centres completely transformed the mental attitude of the derelict, and inspired every surgeon who worked there. The spirit of friendly rivalry and enthusiasm which infected all became part of the atmosphere. Consultations among the members of the staff were of daily occurrence. Any advance made by one surgeon was at once the common property of all. There were no watertight compartments anywhere. The successes and the failures were equally advertised without

mental reservation, and the secretive mind had no place amongst them. Needle-s to say, that spirit of comradeship and interest in each others' achievements and failures could not fail to make for progress. Each surgeon followed his case from the beginning to the end. It did not pass from one department to the other without an agreement as to the continuity of treatment. The surgeon discussed the line of treatment to be adopted with the chiefs of the special departments, and at stated intervals all the cases were collected, so that progress might be recorded and alterations discussed. As time passed, it was found that certain surgeons had special aptitude for dealing with certain types of cases, and they were encouraged to devote themselves to these and refrain from work which others could do better. This principle of employing a special talent and discarding lesser ones will doubtless in time come obtain in our general hospitals, to the great advantage both of the surgeon and of the patient. The growth of surgery has been so rapid of recent years that only a very few surgeons have been sufficiently gifted to deal efficiently with all types of cases, and it is common to hear from old students that certain chiefs were only interested in the surgery of the nervous system, or of the abdomen, or of the extremities, and yet they had to plough through the uncongenial work as best they could. Their brilliance in one department was tarnished by their lower efficiency in another. A spirit of comradeship whereby the staff would interest each other in the work in which they each excelled would result in a sound, practical education, and in impressing upon them their values and their limitations.

The advantage of segregating certain cases under surgeons specially interested in them has been proved by the experiences of war. It was very marked in the case of fractures. In the early days of incomplete organization nearly all the fractures of the femur admitted into special surgical centres exhibited marked malunion and deformity. Some were treated abroad, but most of them were treated in general hospitals in this country. Rapid evacuation at home and abroad due to military exigencies, and, often, defective handling by surgeons with no mechanical training, accounted for an appalling number of deformities, many of which took years to rectify. Later it was recognized abroad that these cases should be segregated, and it was most interesting to note the improvement that occurred. By this time the principle of the Thomas knee, bed, and caliper splints, with modifications introduced to facilitate the treatment of large wounds, was recognized. The cases arriving from the fracture base hospital at Boulogne were invariably so well placed, both as regards fixation and alignment, that they rarely required more than casual attention; when some relapsed into deformity it was due to ill-adviced changes adopted by surgeons at home, who frequently removed the splints too soon, and allowed walking before consolidation had occurred. Cases which had given skilled surgeons abroad the greatest anxiety and endless care, on arriving home failed to secure that continuity of good treatment essential to success. I received many a heart breaking letter from abroad complaining of all this. Several special fracture hospitals were opened in France later, and, as a result, an end came to deformity. After the bombing of Etaples all fractures were sent home, and the expert staffs were housed in our special orthopaedic centres. At one time at Edmonton we had 300 cases of fracture of the femur with an average shortening of less than half an inch. This is an extraordinary achievement when we consider the severity of the injuries. Results equally good were obtained at Alder Hey by the use of the Thomas splint employed in its original simplicity. The lesson we gather from this is that by simple methods taught in a few hours the practitioner in remote places can be safely trusted to start a fractured femur on a safe career.

A general training in the treatment of fractures would have saved thousands of lives during the war. If our universities and teaching hospitals would fix upon the simplest types of appliances, and thoroughly-ground the students in the principles which govern the application, humanity may yet be spared numberless deformities. The appliances should be of the simplest kind to be of widespread use. In every large hospital there should be a fracture ward, and the chief should be both interested and competent. The treatment of fractures in this country is at present a sadly neglected art, and every effort should

be made to place it on a more scientific plane. A walk round our hospital wards indicates clearly the apathy displayed by many surgeons. Fractures are looked upon as a nuisance and generally relegated to a junior house-surgeon, who, in his turn, exhibits but little interest or ingenuity. The surgeon's attention is devoted to the vagaries of the abdominal contents, and he has no desire to waste his time or beds on mere fractures. His attitude of mind finds its reflex in that of the students. The crippling and deformity is looked upon as a necessary sequence of injury rather than as a reproach.

When our military Orthopaedic Centres were started their extension was hindered because we had at our disposal only a few men who had received special training. At that period every young man was expected at the seat of war, and only a very few could be spared for home work. The American Government, realizing our plight, very generously sent us twenty-five well trained young orthopaedic surgeons, who were to help us, free from expense, for the duration of the war. Without that help we should have been very seriously handicapped. In return for this we undertook to train large numbers of their young surgeons at our centres to enable them to be of greater service abroad. This training specially fitted them to deal with injuries of the extremities, and they received an intensive education in the use of a few well considered splints which were standardized by the American Government. These splints were plentifully supplied to the whole of the medical service, together with the code of instructions. By this means in a very short time they were enabled to acquire knowledge which we had learnt only from litter experience. They distributed splints at once to the regimental aid posts; each knew the working of the splint, from front to base, and so continuity of treatment was secured along the line. What a saving of life this represented! Sir Henry Gray, in 1916, collected statistics over one of the army areas, and found that 80 per cent. of compound fracture cases died, mostly before arriving at or after they arrived at the casualty clearing stations; and when, in 1918, immediate fixation in the Thomas splint was secured at the first possible moment, Sir Anthony Bowlby tells us that the mortality was reduced to 30 per cent. This is an interesting reflection in regard to team work, the treatment of shock, and the standardization of simple methods. It would be a calamity if the knowledge forced upon us in such strenuous times and through so much sacrifice were lost in time of peace.

Need for Orthopaedic Training.

We hear frequent criticism from both continents of the lack of orthopaedic training in this country. While lectureships and clinics abound abroad, it is only quite lately—and this largely owing to the war—that there has been a very strong feeling expressed in this country as to our need of orthopaedic instruction. I think this is due to the limited definition which has so long been associated with the term "orthopaedics." So long as the specialty was confined to flat-feet, knock-knees, club-feet, and certain other deformities, it seemed useless to trouble about it. So long as expensive, cumbersome, and consequently useless appliances were in evidence, one is not astonished that the surgeon not only neglected Orthopaedic Surgery but looked upon it with contempt! Fortunately, however, that day is past. It is now recognized that an essential preliminary to orthopaedic efficiency involves a thorough practical training in general surgery. With a gradual expansion of its definition a higher degree of skill is demanded by its votaries, and no one will now venture to practise it with any false notion that the road is an easy one. In addition to operative skill, it demands special qualities of mind; mechanical aptitude and untiring perseverance and patience are not the least important of these.

Since the war several hospitals have decided to embrace in their curriculum the teaching of Orthopaedics, and I have often been asked to help in regard to organization and requirements. An Orthopaedic Department is too often a mere out-patient clinic, sometimes under the control of a physio-therapist with no supervision by a specially trained surgeon. At times a junior man is in control, with no interest but to make it a stepping-stone to another post, which he accepts with alacrity at the earliest opportunity. This is, of course, futile, and can bring nothing but discredit upon all concerned. It is

better to have no orthopaedic department at all than to make it a pretence. The essential and fundamental corner-stone of an Orthopaedic Department is a surgeon who knows his work and intends to devote his life to it. Less than this dooms any scheme to failure.

Organization of an Orthopaedic Department.

At the risk of repeating what I have said in other places I venture to put before you my ideas as to what an Orthopaedic Department attached to a university or teaching hospital should be. Whatever definition of Orthopaedic Surgery is adopted, the general surgeon should have a perfect right to admit into his wards, for teaching or other purposes, any case or as many as he likes included in that definition. The Orthopaedic Surgeon should alone be limited, and should be precluded from treating any other cases except those covered by the definition.

No Orthopaedic Department should be confined to the treatment of out-patients. It should be a complete unit, with beds commensurate with out-patient demands.

The staff should consist of an Orthopaedic Surgeon, who should be in charge of the department and be responsible for its efficient conduct. His practice out of hospital should be confined to Orthopaedic Surgery. He should have a seat on the medical board and hold rank equal to that of the general surgeon. An Orthopaedic Registrar or assistant surgeon, who should be selected as a man desirous of practising Orthopaedic Surgery. A house-surgeon, who should be appointed for at least six months, and clinical assistants and dressers.

The staff should run as a team, in which the nurses play an important part. It is important, therefore, that the matron should give security of tenure to the sisters in charge of the ward and out-patient department. It takes much time and perseverance to train nurses in this particular work, involving, as it must, the application of splints and the renewal of plasters; a considerable responsibility attaches to them. For these reasons they should remain part of the permanent staff.

In a hospital of 300 surgical beds I have estimated that forty should be retained for the orthopaedic service. They should be segregated. The department should have well-equipped physio-therapy rooms under the superintendence of a chief, who should, of course, be a member of our profession.

The orthopaedic registrar (or senior house-surgeon) should hold his appointment for at least two years. If his work proved sufficiently promising, opportunity should be given to him during his tenure of office to visit clinics at home and abroad in order that the hospital work and university teaching should be kept well in advance; this educational course should be financed from hospital funds, and the clinics to be visited could be arranged by the orthopaedic surgeon. The registrarship should be a whole-time appointment, and the assistant surgeon should be understudy to his chief.

The plan of one officer being appointed head of all sections of physio-therapy has much to recommend it. The post is a very responsible one, and presupposes a knowledge of massage, physical exercises, and electro-therapies, and possibly hydro-therapy. Although the physio-therapy department should be closely allied to the orthopaedic, it should still be independent of it, because it is a department used by all the physicians and surgeons.

Difficulties sometimes arise between the chief of the physio-therapy department and the rest of the staff on the question of responsibility. It is well, therefore, to define their relationship clearly in order to harmonize work. The rules which are in force at the Liverpool Royal Infirmary and St. Thomas's Hospital, London, with both of which hospitals I am associated, are satisfactory, and are as follows:

Rules for a Physio-therapy Department.

- (a) In-patients can be sent to the department with general instructions that they require treatment. In such cases the nature of the treatment will be decided by the medical officer of the department, who will be entirely responsible for the case, and who will only refer such cases back at his own discretion or on a definite request from the physician or surgeon who originally had charge of the patient.
- (b) Cases may be sent to the department by the physicians or surgeons with a definite request for certain detailed treatment.

Such cases will be sent back to them at stated intervals. Should any sharp difference arise between the medical officers of the department and the honorary surgeon, the honouaries will take full responsibility.

(c) Cases sent by casualty surgeons should be under the control of the chief of department.

These, or similar rules, will settle the tendency to friction which might possibly occur, but obviously friendly consultation and understanding is the only real basis of good comradeship.

In a teaching hospital with a large out-patient clinic there is a great advantage in starting a workshop for the manufacture of splints. It is not only an economy, but it adds immensely to efficiency, and affords the surgeon an opportunity to develop his mechanical ideas.

The Scope of Orthopaedic Surgery.

When we begin to discuss the scope of orthopaedic surgery, the atmosphere is perhaps not quite so clear. On the one hand, it is desirable not to limit the activities of the general surgeon; on the other hand, it would be unfortunate to deprive the orthopaedic surgeon of work he has been trained to do. The general surgeon is protected by the right he undoubtedly has to treat any case he desires, and justice will be done to the orthopaedic surgeon if he is allowed to admit to his wards those cases which, in ordinary circumstances, he would undertake in private. I think these cases should consist of:

- (a) Congenital and acquired deformities of the spine and extremities.
- (b) Infantile paralysis after the acute stage.
- (c) The deformities of adult paralysis.
- (d) Stiff and ankylosed joints.
- (e) Torticollis.

...oints, such as rupture of crucial ligaments, cartilage, snapping hip, slipping patellae, which are included under the aggressive title of "bonesetting."

I think also that the orthopaedic surgeon should have the right, in common with the general surgeon, to treat recent fractures. If he is competent to deal with mal-united fractures, he should find it easier to prevent deformity than to reconstruct the limb. I have already dealt with the necessity of segregating fractures, and a very healthy rivalry would be maintained between all the surgeons interested in the branch of work if the cases were under close observation in one ward, presided over by nurses specially qualified to nurse them.

This definition admittedly covers a large area of surgery, and for this reason will attract the very best of our young surgeons. These are the men whom we specially desire to attract in order that they may devote themselves to a very intricate branch of work, bristling with problems which require solution, and demanding the highest operative skill.

The Teaching of Orthopaedic Surgery in a Medical School.

Well, given our Orthopaedic Department with its complete equipment and well organized staff, what part is to take in the training of students? It should take place, I maintain, proportionate to the area of work covers.

It is useless to suggest that the student's time is already fully occupied. The endeavour is that it should be better occupied. All the subjects embraced in the definite teaching should be delegated to a department efficient staffed for the work. The student is not asked to give more time, but is offered greater facilities for acquiring knowledge. I do not think that a university or teaching hospital can at first face the problem of training both graduate and undergraduate. The courses should be separate and, in the case of the graduate, he should have facilities for doing a considerable amount of clinical work. The undergraduate training is a more pressing and important problem. My suggestion is that a student more fitted for orthopaedic training towards the end of his curriculum than at an early stage. It is, of course, essential that his attendance be made compulsory for specified number of attendances.

The orthopaedic chief should carefully prepare

systematic course of clinical instruction to be given once a week at an hour which fits into the curriculum, and the student should be required to show at least twenty attendances. The demonstration should last for about two hours. For instance, one afternoon might be devoted to the discussion of club-foot, illustrated by living specimens of every type; the deformity of the newly-born contrasted with that of later life; the nature of the deformities and the effects of weight-bearing; the fundamental principles of treatment governing success or failure; the various gaits and the tests of recovery. All this could be taught with a wealth of illustration, together with a detailed demonstration of the various methods of manipulation and fixation, and of muscle re-education. The student could here have instilled into him the tragedy of removing bone before a preliminary reduction of deformity by forcible means had been effected. The demonstrations should be simple in character, very practical and quite free from controversial matter. Most of his instruction could be given in the out-patient department, which is a more wholesome place for elementary study than the more attractive operation theatre. He should be thoroughly taught, and that by actual practice, the principles underlying the application of plaster and the objects to be obtained by appliances. All this can be done to great advantage if the cases are grouped in such numbers and order as to impress upon the student's mind the difference in degree and type. One afternoon could be devoted to stiff joints, starting with the various types of ankylosis; impressing the importance of position in regard to function; illustrating the various types of arthritis and the differential diagnosis between these conditions and joints bound down by adhesions; the mobilization of joints by safe methods contrasted with those of danger, ending by a practical exhibition of procedure. The student should not be allowed to leave the clinic until he has a knowledge of the practice of physiotherapy. There is no better place than the out-patient department for the teaching of the treatment of fractures of the upper extremities by splints with mobilization. The Orthopaedic Surgeon, in combination with any members of the staff who are interested, should form a committee in order to fix upon the appliances which, by reason of their simplicity and efficiency, may be safely standardized, and the student should be obliged to become thoroughly conversant with their use by frequent exercise in their application, both in the out-patient department and in the wards.

Country Hospitals for Crippled Children.

Country hospitals for children, staffed by well trained surgeons, are essential to any scheme dealing with cripples. Having been associated with such hospitals for over twenty years, I can speak with some authority. I have worked at hospitals where children are indoors day and night, in others where they are out during the day and in at night, and in others where the children are out day and night, and there is no comparison as to their relative values. Children out in the open air day and night are at a great advantage. I think one can prophesy that the time will soon come when the town hospital for children will practically cease to exist. The energy, vitality, and nutrition of the children brought up in open-air wards are a revelation to all who visit them. Infectious disease, the bane of closed wards, never spreads when the wards are fully exposed to fresh air; no matter how low the temperature, the children never take cold. Such a hospital should be attached to every teaching centre, and in every orthopaedic scheme it should hold an important place. This hospital should not be a convalescent home if by the term is meant that no active surgical work is done there. It should be equipped with an operating theatre, plaster rooms, and a physiotherapy installation. In this way nurses can be trained to do special work and obtain their massage certificates—which involve a working knowledge of electro-therapy—and young surgeons gain much-needed experience in the way of practical work.

Some of you may have seen such institutions. We have at Heswall, near Liverpool, due mainly to the vision and generosity of Mr. Andrew Gibson, one of the most beautifully situated hospitals in the world. It lies above the banks of the Dee, surrounded by heather, facing the Welsh hills. One side of each long ward is completely absent; and it is an inspiration to see how everybody—nurses, children, and staff—reflect the joy of living. Treatment

is intensive, for every factor is present which ministers to recovery. The orthopaedic department should have a considerable number of beds in such an institution as this, retaining only a comparatively small number in the town for the more acute conditions and for the purpose of teaching. The surgeons from the city should have their regular visiting and operating days, and some of the clinics should be conducted there.

There is another type of hospital at Baschurch, in Shropshire, which was the first open-air hospital ever built. The wards consist of wooden sheds built upon an open field. The operating theatre and the post-operative wards were largely built by cripples. There are four well known orthopaedic surgeons attached to it—one lives in London, another in Birmingham, another in Oxford, and one in Liverpool. The operative work is all done on Sundays, and each surgeon pays a visit once a month. They are all busy men, and yet, so fascinating is the work and its environment, that they look forward to the visit with eager enthusiasm. This is a sufficient answer to any argument that may be employed in reference to distance. A country hospital in association with a teaching centre need, however, only be a few miles from the city.

This hospital at Baschurch has spread its net over a large area in Shropshire. The difficulty of reaching cases in an early stage and in securing adequate after-care, led to the formation of clinics or subcentres, in small townships. There are at present about seventeen of these. Every week or fortnight one of the house-surgeons, accompanied by an orthopaedic nurse, visits each centre. New cases are examined, treated, or referred to the main hospital. Old cases arrive for reapplication of plaster, splints, or appliances. In attendance at these clinics are usually found a representative from the medical officer of health, the school doctor, the local doctor, and representatives of the invalid cripple aid and child welfare societies. You can imagine how inspiring it is! This association and discussion in remote townships disseminates a spirit of helpfulness and enthusiasm which will largely help to solve the cripple problem. The National Scheme, drawn up by Mr. Girdlestone, and published by us, now in the hands of the Central Committee for the Care of Cripples, was inspired by the work so excellently begun and carried on at these two open air hospitals.

Diplomas and Degrees in Orthopaedic Surgery.

Post-graduate teaching must be prepared for two types of students—a short course for a graduate who can only spare a few weeks, and another of a more intimate kind for those who desire to qualify as expert orthopaedic surgeons. The former will be composed of men who feel the responsibility of not knowing, and should be welcomed and helped, and the tuition should be carefully planned so that the education may be intensive. The university should, however, be prepared with a higher course of training lasting from one to two years, in order to qualify the surgeon to be admitted for a diploma or a degree. During this course the student should be given every opportunity of approaching the subject in its scientific and practical bearing. His curriculum should not allow him an idle moment, and the anatomical, physiological and pathological departments should occupy a considerable portion of his time. If his work has been satisfactory he may obtain a diploma from the university at the end of the first year; and if he studies for the second year he will require to take an assistant's position at one of the hospitals, perform most of the operations that may be required of him in practice, and write a thesis based upon original research. This may secure for him a university degree in orthopaedic surgery. I am pleased to say that, on the initiative of Professor Adams, our Vice-Chancellor at the University of Liverpool, we are engaged in working out the details of such a scheme for the advanced group.

Proposed Orthopaedic Department for the University of Edinburgh.

Now may I be allowed to refer to the University of Edinburgh, which, I am rejoiced to learn, is about to found an Orthopaedic Lectureship? I do this with less hesitation as I am sure that such old friends as Professor Alexis Thomson and Sir Harold Stiles will pardon an enthusiast who loves his art perhaps to the verge of indiscretion. Edinburgh is the largest medical school in

the British Empire, and has traditions envied by all. For generations it was the last word in education. Its graduates are found in every part of the globe, and they display an affection for their Alma Mater and an admiration for their teachers which in my experience is unique. For years I appointed as my house-surgeons Edinburgh graduates, not because of their practical knowledge, which was often deficient, but because they had been carefully taught how to observe. There were many men who had come into closer contact with their patients, who had been given more responsibility, but for receptivity of mind and the ingestion of new ideas the Edinburgh student always excelled. In early days, when views I held were less popular, I know so well their incredulous look, and how closely one had to reason in order to convince. I recall the case of one man, now a distinguished orthopaedic surgeon and a close friend, who, after following my rapid flight around a ward, pushed into the board-room when I was putting on my coat, leaned against the table, and almost angrily pelted questions at me; and when in a timid way I tried to answer him, he clinched all argument by an unanswerable sentence: "This is not Edinburgh teaching." Edinburgh graduates, over and over again, have complained to me of their lack in orthopaedic training even up to recent years.

This is not worthy of a university of so singular a reputation, and which has always displayed an almost fatherly solicitude for the efficiency of its graduates. Now that it is about to make up for its deficiency, I commend for its consideration a scheme such as that which I have advanced. When the work starts let it begin on good lines for defects soon become stereotyped, and are always difficult to amend. At St. Thomas's Hospital in London they have started their department on progressive lines. At King's College in London, also, a distinguished orthopaedic surgeon runs his unit, and has been granted forty beds together with the treatment of fractures. I would like to see the new Orthopaedic Department at Edinburgh add lustre to the glorious traditions of the University.

With the generous gift, which is soon to be expended on a new country hospital, what a magnificent prospect is opened up! It can be started on the most modern lines, with an unequalled equipment. I trust the children will be allowed to live in the open air. Surgeons might renew their youth by working in such ideal surroundings, and the child have the benefit of skilled supervision from first to last. The chronic case could be educated, trades taught him, and a spirit of joy and hope would reign. Those who minister to it in any capacity will realize that they are not only doing a personal and kindly service, but one of invaluable importance to the State. I should rejoice to see such an institution become a national centre for the prevention and cure of cripples in Scotland, spreading its influence over the whole of the land, and conducting an educational and reconstructive campaign of inestimable service to mankind.

REFERENCE.

1 BRITISH MEDICAL JOURNAL, October 11th, 1919, p. 457.

A PRELIMINARY NOTE ON THE USE OF VITEX PEDUNCULARIS IN MALARIAL FEVER AND IN BLACKWATER FEVER.

BY

LIEUT.-COLONEL J. C. S. VAUGHAN, I.M.S.,
LATE CIVIL SURGEON OF RANCHI.

HAVING noted the occurrence of a large number of cases of blackwater fever, and also of very severe malignant malaria in the Ranchi district, I made inquiries as to whether there were in this locality any plant with virtues similar to those of *Aphloia theaeformis* (which is used in these cond.) and was informed that there is such by the aboriginal tribes, and that blackwater fever does actually occur among them was evident enough from the clear description of its leading-symptoms given me by one of themselves, who sent me samples of the leaf of the plant used.

This plant is locally known by various names:

1. Hindi Minjargorwa, Chhargorwa, Chhargorwa, Nagpheni, Nagbail.
2. Uraon Eratakhba.
3. Kol Simjanga.
4. Bengali Baruna, Goda.
5. Assamese Osai.
6. Santali
7. Cachari
8. Garo
9. " Navaladi.
10. Burmese Kretyo.

Of these vernacular names, numbers 4 to 10 have been taken from J. S. Gamble's *Manual of Indian Timbers*, 1902 edition, p. 541. The superintendent of the Royal Botanic Garden at Sibpur has identified the plant as the *Vitex peduncularis* Wall (variety it mentioned also in Kirtikar's and Ba Plants, Part II, page 1001, and figured, but not very accurately, in their plate No. 741. They give its habitat as "Bihar at Parasnath, Eastern Bengal, and Khasia Terai," and state that "in Chutia Nagpur the bark is used for making an external application for pains in the chest (Rev.)

The plant is fully works mentioned above, and in Haines's Nagpur. It is only necessary to add that the leaf characters vary somewhat with the age of the plant, the on the leaf stem being very inconstant in The aborigines state that there is a variety, of vines with a dark-coloured root—they call it a "red root"—and that this is better to use than the usual pale-rooted plant, which, however, is the only kind I have been so far able to obtain and to use.

My information is that it is used in various ways, chiefly as an infusion of the leaves or of the root bark or young stem bark, in fever of malarial type, and especially in blackwater fever. As to the dosage, I followed in the first instance, since October, 1919, and in the main still follow, what amounts practically to the original directions given me by my Uraon informant as regards the method of use. These are as follows:

Two ounces of the leaf used fresh, or dried in the shade, is dropped into 40 oz. of boiling water, and is boiled in it for five to ten minutes, and then allowed to soak in the water in which it has been boiled, for an hour at least. The resulting infusion, amounting to about 40 oz., is poured off the soaking leaf and given as required in doses of about 8 to 10 oz., distributed over twenty-four hours, or given over the day only, the patient resting all night undisturbed. The infusion is of about the colour of strong cold tea and not unlike it in taste, and is given sweetened with a little sugar to taste.

As soon as we decided by the results that the infusion was quite a useful preparation, we attempted to prepare a concentrated infusion on the lines of the infusion *gentianae compositum* (conc.) of the *British Pharmacopoeia*. This has also proved useful, but we found it less reliable than the simple infusion of 1 oz. to 2 oz. of leaf yielding 40 oz. of infusion with plain water. With further experience we found it in certain cases necessary to give larger doses, and to avoid too great a volume in each dose we prepared a 40 oz. infusion from 1, 2, and 4 oz. of leaf, and we called these, for easy reference, infusions of 1 in 40, 2 in 40, and 4 in 40 strengths, and used these as required.

As to results, generally speaking, in malarial fever, we have in almost all instances identified the parasite of malaria before commencing the treatment. This preliminary has only been omitted in a very few of the cases on which this paper is based, and these latter have been, I think, quite undoubted cases of malaria also. The results, as a whole, show that, whereas there are cases that will quite readily yield to a 1 in 40 infusion, there are others that require a very much larger dosage. This may be due to, perhaps, the fact that we have not so far been able to standardize dosage, as the active principle has of course not yet been identified. The actual experience with the use of both the infusion and the concentrated infusion has been that, whereas a proportion of cases have quite readily yielded to a dosage based on the infusion of 40 oz. of infusion from 1 oz. of leaf given over twenty-four hours of administration, and have yielded in some cases in twenty-four hours and in others in the course of seventy-two hours, there have been other cases which have not yielded even in seventy-two hours, but which have yielded at once when the dose was doubled or considerably increased by either giving a larger actual dose of the 1 oz. to 40 oz. infusion, or by using a very much stronger infusion, even up to one of 4 oz. of leaf to the 40 oz. infusion, and there are others which have been even more obstinate. The results, however, have been uniformly encouraging.

The drug seems to have no toxicity at all in the dosages

so far employed, and children have actually been given relatively very much larger doses; indeed, practically the same actual dose as adults, and there are no disagreeable after effects. I append below short notes of some of the cases treated.

As regards the use of vitex infusion in blackwater fever I have so far, naturally, not had much opportunity. I sent out some of this leaf (before we had had it identified) to certain officers of the Forest Department in response to a request from one of them, and it was used in simple infusion in a case of blackwater fever occurring in a forest ranger, and the report is given below abridged out. His urine cleared to a natural colour after nine doses of infusion of 1 oz. of leaf to 40 oz. of water given over forty-eight hours, and he made a complete recovery. I also sent some of the leaf to Dr. A. T. Williams, of Kettelah in Assam, recommending him to try it in blackwater fever, and he had the good fortune to get a very severe case which is referred to below. His telegram to me regarding this case sums it up in the words, "Bad case, ten pints infusion completely cleared specimen, recovery." This infusion was also of 1 oz. of leaf to 40 oz. of water.

I would next briefly review some of the cases treated with the preparations so far used made from the leaf.

(A) MALARIAL FEVER

Case 1—Sister Si, an Indian nun, contracted malaria in Rengari, a very malarial locality, in July, 1919. Had been given quinine freely, which checked the fever, but it always came on again at a few days' interval. Admitted in the latter part of October and treated with gr. 5 quinine sulphate tablets for some days with practically no effect, and with quinquism following. The temperature on October 26th, 1919 was 102.2°, on October 28th, 103°, when malignant tertian parasites were found. Infusion vitex 1 oz to 40 oz. infusion, given in the afternoon and repeated four hourly, and continued until November 3rd. No fever from the morning of October 28th; observation continued until November 7th. No fever all this time and parasites absent from November 4th.

Case 2—Timothy, native Christian. Had suffered for several days from fever and had kept at work, treated with 8 gr quinine tablets t.i.d.s for three days. No effect. Blood examined, malignant rings found, put on infusion vitex 1 in 40, and fever absolutely ceased. Kept in hospital for nine days and on treatment, during which time had no fever; discharged. Under observation for fourteen days. No fever.

Case 3.—P. B. B. Bengali male. Admitted on October 30th 1919. Temperature 104°. Benign tertian. No fever on October 31st or on November 1st. Fever recurred November 2nd, parasite found on the 3rd, and patient put on infusion vitex 1 in 40. No more fever. Under observation for over ten days.

Case 4.—Sister St, Indian nun from Rengari. Fever since July. Repeatedly treated with quinine. The temperature on November 5th, 1919, was 104°, on the 6th 102°, and on the 7th 99°. Malignant tertian parasite found. She was not admitted to hospital, and took at the convent vitex infusion 1 in 40 in half quantities only, with practically no effect until November 15th when she was admitted to hospital and put on full dose. The temperature after this gradually and steadily came down, and, with the exception of one rise on November 23th to 103°, which fell next day to normal, she had no more fever, and has since made a good recovery. In this case it was clear that the half quantity of infusion was too small a dose.

Case 5.—European male adult. Had frequently had severe malaria. Present attack began on October 25th, 1919, with temperature 104°, when he treated himself with aspirin and quinine—the latter in doses of 24 grains daily—until November 5th, on which day blood showed malignant tertian parasites, and temperature went to 105°, and quinine was discontinued. On the 6th put on infusion vitex conc. 1 oz. four hourly. Temperature rose again to 105°, and on 7th to 105.4°. On the 8th he was put on 1 oz. of the infusion vitex conc. four hourly, and temperature fell to 103.6°. On the next day he was put on the simple infusion 1 in 40, and the temperature dropped to normal, and has not risen since.

Case 6.—Mohammedan male, aged about 35. Fever began about December 4th, 1919, and rose on 5th to 105.6° when he came under treatment of an Indian colleague and was put on a fever mixture without quinine. On the 7th the fever fell to

normal, after which he was given quinine sulph., gr. 20. The same evening it rose to 103° and continued at this level till the evening of the 8th, no further quinine being given. On the evening of the 9th it rose again, and on the forenoon of the 10th he was in delirium. I examined the blood on the afternoon of the 11th and from 6 p.m. of that day, malignant tertian parasites having been found, he was put on the 1 in 40 infusion of vitex leaf. By this time he had been continuously in mild delirium for some twenty-seven hours and his temperature was 103.6°. By the morning of the 12th he was free of delirium and of fever and has had no return of high temperature. Vitex was stopped on the 14th. I saw this man again some four months later. He had had no return of malaria during this period.

Case 7.—Hilda, Christian aboriginal, aged 15. Had fever at home on December 13th and 14th, 1919. Admitted with temperature 104° on the 15th. No quinine history. On the 16th temperature 104°. Malignant parasites found next day, and patient put on 102°; on 3, and normal since.

Case 8.—A girl, aged 9. Had had fever for a long time off and on. Admitted to hospital with no quinine history and with a temperature well over 105°. Malignant parasites found on December 16th, 1919, and patient put on 100°, and normal since.

(B) BLACKWATER FEVER.

Case 1.—Dr. A. T. Williams's first case was that of a European tea planter, who had a previous attack of blackwater fever six months ago. He then had a severe neglected quinine prophylaxis and had repeated attacks of fever, generally feeling below par. Had lately been taking a tonic, and felt better. On November 16th, 1919, woke up feeling exceptionally fit after a week of intermittent fever (malaria) during which he had had a maximum temperature of 104° with depression. At 1.10 p.m. passed about 3 oz. of port wine coloured urine. At 2.45 p.m. passed another 6 oz. of the same, and had a rigor and went to bed. Administration of the infusion of vitex leaves 1 in 40 was immediately started. He took it readily and quite liked it. In the evening urine was almost black. By 11.15 p.m. retching and vomiting at 11.30 p.m. rigor, and temperature 102°, clamps in fingers and legs. No sleep. Colour bad; circumoral pallor. November 17th Deep icterus—one large natural stool, pasty, persistent retching and vomiting all day, neither the infusion nor anything else being retained in the afternoon. Iodine acid, hydrocyanic, dil., mustard plasters to epigastrium, and a blister over course of vagus in neck were all tried without success; thirst excessive, mouth very dry. Cramps; vomited matter scanty and "coffee grounds." Rectal salines given copiously. Pulse kept astonishingly good. Total urine of twenty-four hours was 57 oz of deep claret, almost black, colour. Rectal feeds from the evening November 18th: Prostration excessive. Champagne, salines and food by rectum. Three six ounce feeds retained in twelve hours. Vomiting seemed checked by further acid, hydrocyanic, dil. Urine began to clear noticeably about noon and continued to clear through the day. Very restless at night. Morphine gr 3, thirst severe, sleep very broken till 3 a.m. of 18th-19th, and then good till 6.30 a.m. of 19th. November 19th: Marked improvement, no vomiting retching quietly, thirst less, urine steadily clearing and almost clear by night. Secretion of urine less. November 20th Urine quite clear. Went right ahead from this onwards, and never looked back.

The urine began to clear forty-eight hours after the infusion was started and continued to clear in spite of a rise of temperature on November 18th. Nothing was given except the infusion. The total amount drunk was approximately 10 pints, but the first five pints were only half strength.

Case 2.—Dr. Williams's second case was that of a Bengali clerk, who is alleged to have had two previous attacks. When first seen he had almost complete suppression of urine and severe vomiting. He took about 2 pints of the infusion and refused to touch any more. Everything was tried to get his kidneys going, but without effect. A catheter specimen, obtained about six hours before death, was much clearer than the first lot seen. (These cases of Dr. Williams's are given practically in his own words.)

Case 3.—On November 22nd I received a telegram from the Forest Officer at Manharpur, stating that a forest ranger was down with blackwater fever and asking for vitex leaf (which had not then been really identified botanically). I sent some at once, but it was not until the evening of the 27th that the patient received them. Administration of vitex infusion was

Infusion of vitex 1 in 40 was given from 8.15 p.m. on November 27th, and continued regularly every four hours till noon on December 3rd, when it was stopped. No other drug was employed. The urine which was blackish red on November 27th, began to clear on November 28th, became natural in colour about 6 p.m. on November 29th, and continued so

begun at once and continued four-hourly. The urine cleared in thirty-six hours and the temperature dropped.

Besides the cases noted in this paper we have treated with vitex in Ranchi some 60 cases of malarial fever, and we have under treatment a case of blackwater fever which occurred at Rengari in a European nun.

This patient had recovered from the original attack of blackwater fever under treatment with *Aphrocia theaeformis*, and was brought into Ranchi with her urine still very dark and with abundance of bile in it, and obviously on the edge of a relapse. She was a very severe case to start with, and was in a very critical condition on arrival here. Under infusion of vitex (2 in 40) her urine absolutely cleared in thirty-six hours, her fever came down, and she has made a very good recovery so far.

Now to sum up the results generally. It must, in the first place, be strictly borne in mind that we are but at the very beginning of a very important investigation. It must not be forgotten that in the treatment of malarial fever with quinine—taking the average results of all practice—we get very varying results. There are cases treated with quinine which yield at once in the most gratifying fashion very shortly, if not immediately, after the commencement of treatment. There are others which yield after a week or so, others which persist longer, and others, again, of obstinate types which yield only after the most drastic treatment, or after prolonged treatment, and we are tempted in some few of these latter to ask what the real effect of quinine has been, and whether it has really had any effect. We are accustomed to regard quinine as the specific for malaria, and in prolonged cases yielding only after an obstinate fight we say in practice that quinine has succeeded only after a determined exhibition of it. I am referring now to cases of undoubted malaria. Now, with vitex my experience has been that we have had the same series of varying results—namely, cases that yield at once, others which yield after a short period, others which persist, and others which yield only after a prolonged struggle; and we have had with vitex no experience at all comparable to that of the giving of alkaloids of quinine hypodermically or by intravenous injection. All this, as regards quinine cases, is familiar to most men practising in malarial countries.

There is, however, one very important point of difference at this stage of our investigation, for with quinine we have the finished article worked out to a nicety. The original article was a wild South American forest plant, and now we have all its alkaloidal products differentiated, and the alkaloids have doses that are standards unto themselves and recognized as such. We know the clinical standard value of each of them, and when we come to use them we more or less know what we are dealing with—more with reference to the chemical constitution of the drug we are using, less with reference to what I may perhaps allude to as the coefficient of virulence and resistance to drugs of the particular malaria under treatment. With these two opposing factors we get our varying clinical results with quinine and its allied alkaloids—that is to say, with a series of drugs which have something of a recognized clinical standard value of efficiency. On the other hand, vitex is at present in the stage approximately in which cinchona was when first discovered in the Peruvian forests. The cases I record are the very first fruits, and the singular value of these first observations lies in (1) the extraordinary parallel in the types of the results of treatment with quinine on the one hand and vitex on the other; (2) the extraordinary general result of cure which, so far, has been uniform as with quinine. It must be borne in mind that vitex is now in the position in which cinchona was when first discovered—a drug used only in the crudest way by aborigines. The way in which I have so far used it is the aboriginal method. Its results have been good.

I would next point out certain further details and differences.

1. Quinine is extremely bitter; vitex is not so.
2. Quinine produces many troublesome effects and after-effects which I need not dilate on, and is toxic. Vitex produces nothing approaching quininism, and seems to be absolutely non-toxic, and, so far, has given no unpleasant after-effects.
3. Quinine is known to have definite depressing effects on the heart and circulation; vitex, after its use, produces a feeling of well-being, is mildly stimulant, appears to have no depressing effect on the heart, and has a clear diuretic effect.
4. Quinine is oxytocic, and there are dangers in giving it in pregnancy. Vitex, as far as our experience of it goes, has apparently no such dangers attending its administration.

It would appear, therefore, that in *Vitex peduncularis* it may yet be found that we have a most valuable remedy for malaria, and that all that is needed is to work out its properties in detail.

I would add one interesting point which, however, needs investigation. Mr. McLeod Smith, the subdivisional officer of Simdega, tells me that during the last outbreak of influenza in 1918-19 those villages that were accustomed to use this plant for malaria used it in the influenza outbreak and had a mortality definitely lower than those other villages which did not use it. This is but a loose observation from a layman, but acting on it I have so far used it in a few cases of obvious influenza which have recently occurred, with a complete relief resulting after three doses in twenty-four hours of the 2 in 40 infusion of leaf. I give this for what it may be worth as an isolated observation, but I shall push it if opportunity offers.

The root bark and stem bark are also about as useful as the leaves for all purposes for which the latter may be used. This is to a large extent confirmed in my experience.

The infusion of leaves and bark is said to be useful in cystitis. I have found it so in one case. I certainly find it an excellent diuretic.

In vitex it may be that we shall find active principles which will give us all the power of quinine in malaria without many of the dangers and drawbacks of quinine and its allied alkaloids, and we have the most important additional clinical value of this plant in blackwater fever, the scourge of our forest areas and of the submontane tea districts. If future investigation confirms the value of this plant in malaria, it must be strictly preserved in the forest areas of the country. It is widely distributed, perhaps, but none too abundant where it occurs. One may find a hundred plants on a single acre, and travel over miles of forest before he comes across another plant.

Finally, I must express my obligations to all who have helped me in this investigation so far; to Kuril Kerketta of Kurukela in Ranchi District, my aboriginal informant, who put me on to the leaf and plant; to Mr. David McLeod Smith, subdivisional officer of Simdega in this district, for his keen all-round help, and for much information as to the aboriginal and local names of the plant and its local uses, and for collecting the leaves and bark; also to Mr. E. Durham-Waite for the first clear botanical specimens put up; and to Miss McDonald and Dr. Arit of the Society for the Propagation of the Gospel Mission Hospital, and to Mother Henriette of the Ursuline Convent at Ranchi, and Assistant Surgeon Garib Das Gupta at Ranchi, and Subassistant Surgeon Khudiram Mukerjee of Simdega, for all the help they have given me in various ways in clinical work, and in collecting leaf and bark.

DETAIL OF PREPARATION SO FAR USED.

1. Infusion of leaf—in three strengths, as detailed in the foregoing notes—1 in 40, 2 in 40, 4 in 40.

2. Concentrated infusion of leaf.

Powdered leaf	8 oz.
Sp. vin. rect.	2 1/2 oz.
Aqua chloroformi	ad 12 oz.

Make up to 12 oz. with aqua chloroformi after a week's percolation and straining off liquid. Dose: Half to one ounce every four hours. Found as good as leaf infusions (1).

3. Fresh stem bark extract.

Ground bark	4 1/2 oz.
Sp. vin. rect.	6 oz.
Aqua chloroformi	ad 30 oz.

Percolate for a week, and make up liquid with aqua chloroformi to 30 oz. Dose: Four to six teaspoonfuls every four hours. Found about as effective as leaf infusions (1).

DILATATION OF THE HEART.

BY

D. W. SAMWAYS, M.D., D.Sc., M.R.C.P.,

MENTONE, FRANCE.

THE mechanical disadvantages under which a dilated heart labours are not likely to be adequately realized till the influence of size on the working conditions of the heart is more fully grasped. The heart is commonly thought of as so much muscle, better or worse nourished, and better or worse controlled; whereas the factor of the size of the chamber it encloses is largely overlooked, though of immense importance to its working.

Now, if four lines be drawn from the centre of two concentric spherical surfaces through both surfaces, as in the diagram, the diameter of one sphere being double that of the other, the area enclosed between the points of passage of the first surface will obviously be but one-quarter of that for the second.

If a sphere dilate, therefore, to twice its diameter or radius, it would have an internal surface area four times as large as before, and its walls, to cover that greater surface, would necessarily become four times as thin. It

may be objected that the heart is not a sphere; the same principle, however, applies, so that if the heart were dilated to double its diameter its inner surface would be approximately four times as large, and the heart walls four times as thin. For this reason alone it would be roughly four times as difficult for the heart to contract on its contained blood, there being four times the area of blood to contract on, or four times the

number of units of area of blood to resist its contraction.

This, however, is not the whole difficulty, for the heart's power of exerting a pressure on its contents becomes halved when its diameter is doubled, so that while the work to be done is quadrupled, the working power is halved. or, in other words, the heart's embarrassments are increased eightfold.

The proof that the working power of the heart is thus lowered may be presented as follows: The force with which a hollow rubber or muscular sphere can contract on its contents is merely the force with which one-half of the sphere can pull the other half towards itself, and is measured by the pull across any circumference.

If p = the pull of a unit of muscle;

c = the length of circumference, which is $2\pi r$, where r is the radius;

t = the thickness of muscle at the circumference;

then $pc t$ = the pull across the whole circumference drawing the two halves of the hollow sphere together, and so compressing its contents.

Now $pc t$ is the same as $p2\pi r t$, but I have already pointed out that t , the thickness, becomes four times less when r , the radius, is doubled.

When, therefore, the sphere is doubled in radius or diameter the pull across the circumference is doubled in virtue of the circumference being double as long, but it is one-quarter in strength in view of the fact that the muscular material is only one-quarter as thick. On the whole, therefore, the pull is halved.

If the sphere were further dilated, say to three times its former radius, the pull would amount to $p2\pi 3r \frac{t}{9}$, or, in other words, it would gain threefold by the increase in circumference, and lose ninefold by the decrease in thickness, since the thickness decreases inversely as the square of the radius, as already shown.

Though the heart is not a true sphere it is a hollow roundish viscus, and, in its measure, is subject to the same physical principles. When enlarged it has more units of surface of blood, increasing, more or less, as the square of the diameter to resist its pressure, and it has less power to contract, the power changing in inverse ratio to the diameter.

From these two causes combined, the compression the heart can exert on its contents would decrease eightfold if the diameter of its chamber were doubled, and twenty-seven fold if the diameter were trebled—that is, it varies always inversely as the cube of the diameter or radius.

As applied to the heart or any hollow viscus in the body, such as the bladder or uterus, these figures must not be taken as of any definite value, other than showing a physical principle to which they are subject, and the immense mechanical drawback of dilatation.

This consideration shows why "breaking the waters" when delivery is well advanced is followed by such powerful contractions on the foetus. It is quite likely that the contractions are no more powerful than before, but merely more efficient. The surface to contract on is smaller, and the two halves of the uterus can be drawn towards one another with more force, simply because the uterus is thickened. With less to contract on and a thicker contracting wall no increased muscular effort is required to produce an enormously increased expulsive effect, the pressure on the foetus could, more or less, rise inversely as the cube of the decrease in diameter.

A dilated heart may be greatly relieved by blood-letting, because it allows the distended ventricle to contract; and, once contracted, the muscle wall may, at least for a while, prevent its chamber from becoming over-large again, for it is much easier to keep a chamber small than to reduce it when once large.

I have endeavoured to show in many papers in the BRITISH MEDICAL JOURNAL and elsewhere, in the past, that the same physical principle applied to the auricle probably explains most that is puzzling in the behaviour of the heart in mitral stenosis. The presystolic crescendo murmur and its running up to and into the first sound, the absence of ventricular regurgitation through an incompetent mitral valve, the presence of regurgitation and a systolic murmur replacing the presystolic when the auricle later on dilates and allows regurgitation into it, and so on.

The important thing, however, to first realize is that the size of the cardiac chamber at any time determines, more than is readily imagined possible, the power of the heart to empty itself, the heart weakening, as it dilates, inversely, more or less, as the cube of the dilatation.

A STUDY OF THE PNEUMOCOCCUS AND STREPTOCOCCUS GROUPS IN THEIR RELATION TO INFLUENZA.

BY

W. R. LOGAN, M.D., F.R.C.P. EDIN.,

CLINICAL PATHOLOGIST, ROYAL INFIRMARY, EDINBURGH.

(Abstract of Report to the Medical Research Council, from the Research Laboratory of the Royal College of Physicians, Edinburgh; Professor James Ritchie, Superintendent.)

THE object of this investigation was a study of the pneumococci and streptococci from cases of epidemic influenza, firstly in their relation to the earliest stage of illness, when the infection was presumably a comparatively pure one; and, secondly, with regard to their part in the more advanced cases, when pulmonary complications had set in.

The preliminary portion of the inquiry was directed to questions of technique. It was necessary to define precisely what constitutes a pneumococcus and what a streptococcus, and what criteria may be adopted for distinguishing various types of these organisms from one another. It was concluded that, while there are various properties which, if taken together, may serve to distinguish the pneumococcus and streptococcus groups from each other, there is only one test which, if used as a single test, can serve to differentiate the two groups—the bile test. The solubility of pneumococcus in bile, apparently an empirical reaction, is nevertheless an indication of a specific chemical constitution of the pneumococcus, which it does not share with the streptococcus group. This test was then adopted as the invariable means of distinguishing the two groups, while the other tests in common use—inulin fermentation, presence of capsule, type of colony, morphology, virulence to mice, power of growth in certain media, homogeneity or granularity of growth in plain broth, etc., were used only as secondary confirmatory tests.

The methods adopted for differentiating the different types of organisms within these two groups were for the pneumococci serological, agglutination tests with the Rockefeller Types I, II, and III serums being carried out; for the streptococci, biochemical, fermentation and haemolytic tests being used.

The cases studied may be taken as typical of those occurring in the Edinburgh district during the second and third waves of the epidemic, that is, during those outbreaks which reached their height in November, 1918, and in February, 1919. One hundred and eight cases were studied completely from the point of view of their

* Advance reports on this subject have already been communicated as follows: (1) Preliminary Report to the Medical Research Committee, April, 1919; (2) Paper read before the Edinburgh Medical-Chirurgical Society, May 14th, 1919, and published by the *Edinburgh Medical Journal*, July, 1919; and (3) Paper read before the Pathological Society of Great Britain and Ireland, July, 1919; the Report (4) of which the present paper is an abstract was sent to the Medical Research Committee in April, 1920, and will be published in the *Edinburgh Medical Journal*.

pneumococci and streptococci; seventy-five were civilians, the remainder soldiers.

Specimens from cases of "pure influenza" were usually taken during the first three days of illness; from cases with pulmonary complications naturally, as a rule, at a later stage, varying from three days upwards. From the former group of cases nasopharyngeal swabs were usually employed; from the latter, sputum. Forty of these specimens were plated out direct on media suitable for pneumococcus; in the remaining sixty-eight a preliminary passage through mice with subsequent plating from heart blood and peritoneum was used along with direct plating of the specimen on suitable media.

The Incidence of Pneumococci and Streptococci in the Cases.

Pure Influenza Cases.—In this group of cases pneumococcus was isolated from 6 out of 44 cases, or from 13.6 per cent.; while streptococci were obtained from 44 out of the same 44 cases, or from 100 per cent.

Cases of Influenza with Pulmonary Complications.—From the second group of cases pneumococci were isolated from 50 out of 64 cases, that is, from 78.1 per cent.; streptococci were isolated from all the 64 cases, or 100 per cent.

It was therefore possible to draw the conclusion that the pneumococcus group played little part in the cases of pure influenza, and could therefore be excluded from the list of suspected initiating agents; that its great increase in number in the cases suffering from pulmonary complications, having in mind the known pathogenicity of many pneumococci, suggested an important rôle in these complications. It was further shown that streptococci were invariably present in both simple and complicated cases.

The next step was therefore to ascertain if these pneumococci in the secondary complications were of one type, and similarly if the streptococci of the simple and complicated cases differed on the one hand from each other, and on the other hand from the streptococci normally inhabiting the mouths of human beings.

Types of Pneumococci Present.—Fifty-one strains of bile soluble diplococci from 34 cases of influenza were typed out, using Rockefeller I, II and III serums. Of these 34 cases three yielded Type I pneumococcus, three Type II pneumococcus, two Type III pneumococcus, and 26 pneumococci of Group IV. An attempt was made further to subdivide the Group IV pneumococci with the object of determining whether those present in influenza were or were not the same as those sometimes obtained from healthy throats. The attempt was unsuccessful.

Types of Pneumococci in relation to Types of Clinical Case.—The eight strains of Types I, II and III pneumococci were, with one technical exception, derived from cases with well-marked pulmonary involvement, in each case with consolidation, shown either clinically or at post-mortem examination. The exception was a case of "pure influenza," showing no pulmonary symptoms at the time a Type I pneumococcus was obtained; she manifested pulmonary symptoms within a day or two and died within a week of pneumonia. One of the Type II pneumococci was from a lobar pneumonia in which the existence of influenza was doubtful.

The Group IV pneumococci were derived from cases of pure influenza; from cases of influenzal bronchitis; from cases of influenzal bronchopneumonia; and from cases in which, as shown both clinically and by post-mortem examination, extensive consolidation was present. They were isolated from cases in which the illness was trivial, from cases in which a very chronic chest condition supervened, and from cases with a rapidly fatal termination.

Incidence of Haemolytic and Non-Haemolytic Streptococci.

For the purpose of differentiation the action on blood agar was employed.

One hundred and nine strains of streptococci derived from 57 cases were subjected to the test. From 28 cases of pure influenza haemolytic streptococci were not once obtained; of 29 cases with pulmonary complications, 8 yielded haemolytic streptococci, or 28 per cent. of these complicated cases.

The Haemolytic Streptococci.—The same conclusion was thus arrived at with regard to the haemolytic streptococci as had been come to concerning the pneumococci; there was evidence that they played no part in the production of pure influenza, but they were apparently active as secondary invaders of the lung in more than a quarter of the cases with pulmonary complications, as compared with the figure of three-quarters of the cases obtained for the pneumococci.

The Non-Haemolytic Streptococci.—These were obtained from all the cases examined save two. In these two, haemolytic streptococci were obtained in the culture, in one from lung

substance (post mortem), in the other from empyema pus. Holman's classification for the non-haemolytic streptococci was adopted. Ninety strains, derived from 46 cases, were tested in this way. Seventy-seven of these were grouped as follows: *faecalis*, 0; *non-haemolyticus* I, 1; *mitis*, 44; *salivarius*, 26; *non-haemolyticus* II, 1; *non-haemolyticus* III, 0; *equinus*, 5; of the remaining 13 strains, 9 were either *mitis* or *salivarius*; 4 either *faeca*. The 90 strains may therefore be *mitis* or *salivarius*, while 11 were of other varieties. As regards their case incidence, either *mitis* or *salivarius*, or both, were obtained from 21 out of 22 cases of pure influenza; while either *mitis* or *salivarius*, or both, were obtained from 22 out of 24 cases with pulmonary complications.

Assuming Holman's tests to be adequate for the differentiation of these organisms, one would be able to conclude that their presence in cases of influenza is not significant of an infection from without, as such types are met with in normal mouths. Evidence will be produced, which cannot be given in detail here, to show that Holman's tests are not adequate for this purpose. Taking other factors into consideration, however, the conclusion was arrived at that it was in the highest degree improbable that organisms of this group were responsible as initiating agents in the epidemic; while as to their rôle in the secondary complications, there was little doubt that some members of this group, possibly even the saprophytic varieties, played a part in the complicated cases.

Summary of Conclusions.

In this brief summary of the results obtained proof of many of the statements has necessarily been omitted; these proofs will be included in the detailed paper. Here I may add some of the main conclusions. Only the pneumococcus and streptococcus groups are dealt with.

It was shown that pneumococci and aerobic streptococci could be cleared of suspicion of acting as initiating organismal causes in the epidemics; that the pathogenic organisms of these groups which were associated with the production of pulmonary complications were of a variety of types; that many of these were definitely infections from without, while with the remainder limitations of technique prevented exact proof as to their origin being brought forward; that the presence of saprophytic streptococci and of presumably saprophytic pneumococci in the lungs of many advanced cases may be explained as a late invasion of the already diseased lung, either by the patient's own mouth organisms or by the saprophytic mouth organisms passed on from another patient, while their presence in the sputum is, in many cases, due simply to the contamination of the specimen with organisms from throat and mouth.

Both from the point of view of the history of the individual case and from that of the history of the epidemic itself, one may divide influenza into three stages: a primary stage, when the unknown infecting virus, whether it be Pfeiffer's bacillus or some other organism, is apparently acting alone, though presumably frequently accompanied by other organisms which may or may not later be able to develop a like activity; a secondary stage, when pathogenic pneumococci and streptococci are active in producing pulmonary complications, either alone or along with other pathogenic organisms; and a tertiary stage, when saprophytic mouth organisms may invade the already diseased lung.

It was shown that the type of pulmonary complication is to a considerable extent dependent on the type of pathogenic pneumococcus or streptococcus present; that pneumococci of Types I, II and III were associated, as was to be expected, with pneumonias showing definite consolidation, as were also certain of the Group IV pneumococci; that others of the Group IV pneumococci and the haemolytic streptococci were associated with complications of the bronchopneumonic and bronchitic types.

The presence of complex infections in epidemics of this kind does not imply that the original bacterial cause at the beginning of the outbreak was not a single type of micro-organism; nor does proof that the important organismal varieties are always types foreign to normal mouths and throats—are in fact infectious from without—imply that the real primary agent in such epidemics may not be a temporary susceptibility, individual or general, due to causes at present unknown.

FRACTURE OF THE FIRST RIB.

BY

E. T. C. MILLIGAN, O.B.E., M.D., B.S., F.R.C.S.,
SURGEON TO DREADNIGHT HOSPITAL, GREENWICH, AND THE
WEIR HOSPITAL, BALHAM.

AND

R. E. FORD, M.B., B.S. SHEFF. AND LOND.,
HOUSE SURGEON, WEIR HOSPITAL, BALHAM.

THE following case of fracture of the first rib is interesting, both on account of its rarity and its clinical similarity to a cervical rib or exostosis.

A female, aged 17 years, complained of a swelling in the right side of the neck. The patient was unaware of its presence until it was noticed first by another girl. She had had "pins and needles" in the right hand and cramp in the arm for some time, and attributed this to an accident two months earlier, when she fell down a few stairs. She did not remember her attitude in falling, nor did she notice pain, tenderness, or bruising. The cramp was felt when the arm was hanging by the side and was relieved by rubbing.

Examination showed a hard bony swelling 1 in. above the middle of the right clavicle, fixed and irregular but somewhat rounded in outline, about the size of a walnut. It was continuous, both in front and behind, with the first rib, into which it merged. The space between the middle of the clavicle and the swelling was too narrow to allow the examining fingers to be inserted. There was a slight falling backwards of the anterior end of the clavicle. Between the swelling and the skin the pulsations of the subclavian artery, which was displaced upwards and outwards, could be seen and felt distinctly, giving also a thrill and bruit. The cords of the brachial plexus situated immediately behind the pulsating artery were similarly displaced, and could be rolled over the subjacent swelling with the examining fingers. The radial pulse was altered in volume and force when the arm hung by the side. Sensation and muscular power were unimpaired, and there was no wasting. Fracture was confirmed by x-ray examination.

The unique features of this case are the displacement and the clinical signs and symptoms.

Displacement in fracture of the first rib is quite rare. In the case recorded displacement was the main feature, attracting the notice of others to the swelling in the neck, and causing pressure signs and symptoms. In the literature there is an instance of slight displacement causing the normal curve of the rib to be slightly angular. If it is remembered that the first rib has superior and inferior surfaces with internal and external borders, it can be seen that angular displacement would more likely be upwards or downwards than outwards, which is the case in other ribs with internal and external surfaces and superior and inferior borders.

Complications usually draw attention to the fracture hitherto unnoticed, so that probably the frequency of complications has been exaggerated, uncomplicated fractures being no doubt overlooked. Abscesses above and below the clavicle have required incision and drainage. Empyema, lung abscesses, even rupture of the pleura and lung, followed by death, have occurred as complications. The case now reported is unique in its relation to the subclavian artery, which with the brachial plexus is displaced upwards and outwards.

Site of Fracture.—Fracture at the site of injury occurs by direct violence applied to the posterior and also to the anterior part of the first rib. These areas are protected by the posterior shoulder girdle muscles and the inner end of the clavicle respectively, so that great violence is needed to cause fracture. The costal cartilage and junction of the costal cartilage with the first rib have also been the site of fracture. Any part of the rib between its two extremities is subject to fracture, and the deformity, angulation upwards and outwards, would fairly suggest compression force applied from either end. Thus part of the rib is shielded from direct violence by overlying structures. It has been suggested that the clavicle might act as a powerful lever, fracturing the underlying rib, like the top lever of a nutcracker, trauma on the shoulder representing the power. This mechanism can only act very rarely, if at all, and in abnormal relations of clavicle to first rib, else fracture of the first rib would be a common occurrence, for injuries and falls on the shoulder are very frequent.

Symptoms and signs are usually so slight as to pass unnoticed, or are overshadowed by concomitant injuries. Indeed, the fracture has very often been discovered during

the investigation of its complications. Still, in a few cases localized pain on breathing, or moving the shoulder girdle or neck, has been felt.

Union is the rule, as in all ribs, yet a case has been described of pseudarthrosis at the site of fracture. In the case here reported there is firm malunion.

A CASE OF MYOCLONIC ENCEPHALITIS LETHARGICA SIMULATING HYDROPHOBIA.

BY

STANLEY E. DENYER, C.M.G., M.D., M.A. CAMB.,
F.R.C.S. ENG.,
PHYSICIAN, HULL ROYAL INFIRMARY.

AND

D. E. MORLEY, M.D., B.S. LOND.,
DARTON-ON-HUMBURY.

IN the discussion on epidemic encephalitis in 1918, at the Royal Society of Medicine, Dr. Crookshank pointed out that the old physicians used to describe "hydrophobia without the bite of a dog," and that this condition had also been reported in England in 1918. The following case was one in which hydrophobia was thought to be a possible diagnosis.

A. B., female, aged 25 years, up to the morning of November 11th, 1920, was in good health, and with the exception of three attacks of influenza had had good health for many years. On the evening of November 11th she did not feel well; on November 12th she gave up her usual occupation owing to increased feeling of illness. She was first seen by one of us (D. E. Morley) on November 13th, and appeared to be suffering from a mild influenza attack with no special symptoms. When seen on the 14th she was distinctly excited and anxious about herself; she had vomited in the morning, and headache had become a more marked feature. On November 15th, when seen (by D. E. M.) she became, as she had been earlier in the day, maniacal. Sitting up in bed, she shouted that her mouth was paralysed and that she was going to die. The left side of the face was weak but there was no definite paralysis. On the 16th she was wildly delirious, the most marked feature being dread of trying to swallow, and the prolonged laryngeal spasm caused by the attempt to do so. The same ideas of paralysis and death still pervaded her delirium. The condition was such as one would expect to find in a case of hydrophobia, only there was no reasonable excuse for such a diagnosis.

On November 17th she had subsided into a semi comatose condition and was seen in consultation (with S. E. Denyer). Encephalitis lethargica was diagnosed. The condition found (by S. E. D.) was as follows: Temperature 100°, pulse 88, good; limbs flaccid, no trismus, slight twitching of the facial muscles on the right side, pointing to irritation of the seventh cranial nerve. She also had occasional clonic movements of her arms. The knee jerks were present, no Babinski, no ankle clonus, tendo Achillis jerks not obtainable, no Kernig's sign. On stroking the foot fairly hard, irregular twitching of the muscles of the outer side of the thigh took place. There had been no incontinence of urine or faeces until this day, when there was a slight incontinence of urine; the bladder was empty. Pupils react to light but are unequal, the left being slightly dilated. No nystagmus. She was in a lethargic state and did not answer questions or appear to be aware of anything that was going on. There was great difficulty in swallowing, owing to the marked laryngeal spasm. A fluid of purulent appearance was frequently regurgitated from the throat. There was subcutaneous emphysema at the root of the neck on the right side. *Tache cerebrale* was present. The abdominal superficial reflex was present. There was no squint or ocular paralysis, no cyanosis, no sweating, no rash, no retraction of the head or pain in moving the neck in any direction. She had been fed successfully with a nasal tube previously, but an attempt to repeat this set up a condition of spasm which made feeding impossible by this means. She was therefore given saline enemata containing sugar, and to these was added 40 grains of hexamine every eight hours.

This treatment was continued, and on November 19th 10 grains of hexamine was administered intravenously. On November 20th she was conscious, and a further 20 grains of hexamine was given intravenously. On November 21st she was much improved mentally, being conscious of her surroundings and able to speak sensibly, though her words were incompletely formed. Feeding now became possible by a stomach tube, though there was still considerable spasm until the tube was in position. Her general condition, however, became worse, and although the emphysema at the root of the neck which had been so marked on November 17th had completely gone, bronchopneumonia supervened and the illness terminated fatally on November 24th.

The temperature varied from 100° to 102°, with the exception of rises to 104° and 105° on the third and fourth days of the illness.

The indications seemed to point to hexamine being of value. The cause of death seemed to be the result of the rupture of one of the constrictor muscles of the pharynx, due to extreme spasm, causing subcutaneous emphysema, with resulting cellulitis and aspiration pneumonia.

CARDIAC MASSAGE IN RESUSCITATION.

PROFESSOR GUNN'S most interesting article on "Massage of the heart and resuscitation," in your issue of January 1st, 1921, leads me to think that it will be of interest to record a case which supplements his experimental findings by some clinical observations.

An adult female, suffering from carious teeth. General anaesthesia was induced with ethyl chloride, and three teeth were extracted without difficulty. Cessation of respiration and sudden pallor immediately ensued. Ether was injected subcutaneously and artificial respiration begun. As the pallor increased, the heart was auscultated and found to have stopped. Artificial respiration was persisted in for about three minutes from the time of cessation of respiration in the hope that the cardiac inhibition would prove a temporary one, but it was of no avail. The abdomen was then opened, and cardiac massage begun. With the other hand artificial respiration was maintained by compression of the chest. Pituitrin 1 c.cm. was given. Almost immediately returned to the face of the artificial circulation. After about five minutes' massage, feeble spontaneous heart beats were felt, and were supplemented at intervals by massage. About two minutes later several deep spontaneous respirations were made in rapid succession. This was at once followed by arrest of the heart and respiration also stopped again. Cardiac massage and artificial respiration were persisted in for forty-five minutes, during which time deep inspirations were made at intervals of about ten seconds—as in morphine poisoning. At first deep, they became shallower and more infrequent, and eventually ceased.

This case is of interest in the light of the theory which Professor Gunn has advanced. Professor Gunn suggests that certain cases of failure in resuscitation by cardiac massage and artificial respiration are due to vagus inhibition. In such a case the heart has commenced again to beat well, after massage; the paralysed central nervous system, including the respiratory and vagus centres, begins to recover; spontaneous respiration begins; then the vagus centre awakens, hyperexcitable after its paralysis, and cardiac inhibition results. From cardiac arrest due to this cause Professor Gunn states that he has been unable to resuscitate animals.

In the case described this sequence of events is closely followed. The heart was initially arrested by vagus inhibition, due to stimulation of the fifth cranial nerve. Cardiac massage and artificial respiration revived the brain. Spontaneous respirations began, immediately followed by cardiac arrest, presumably due to inhibition by the recovering vagus centre. If, as Professor Gunn recommends, atropine had been administered intravenously, it seems probable that this patient would have recovered.

NORMAN M. DOTT, M.B., Ch.B. Edin.

Edinburgh.

A CASE OF DELAYED ARSENICAL POISONING.

THE length of time (three months) which elapsed from the taking of arsenic to the fatal result, the large quantity taken, and the nature of the symptoms in the slow poisoning of the nerve tissues, all make this case of interest from a medico-legal point of view, though the taking of the drug was purely accidental, and not the slightest suspicion of attempted suicide ever arose.

Mr. X., aged 68, proprietor of a grocery establishment, who carried on also an extensive pharmacy, had been under my care for some time, suffering from enfeebled action of the heart, but not sufficient to prevent him from following his usual business. At 8 p.m. on February 23rd, 1920, he took by mistake for a preparation of magnesia, which he was in the habit of taking for indigestion, a heaped teaspoonful of arsenic mixed with hot milk; the quantity when weighed equalled 180 gr. Half an hour later he ate a hearty supper of porridge and milk. At midnight he began to vomit, had diarrhoea, and complained of a burning sensation in his stomach. The diarrhoea and straining continued with increased violence

until 3 a.m. When I arrived at 4 a.m. I found him cold, with thready rapid pulse. He was vomiting, and had watery diarrhoea with great tenesmus. Water was at once rejected; the temperature was subnormal, and the pulse 120. He complained most of cramps in his legs and intestines, and a burning feeling in the pit of the stomach, with vomiting and diarrhoea every few minutes. He was quite conscious, and wrote an account of how the accident occurred. I decided with Dr. D. C. Campbell, who had arrived also, that it would be useless to wash out the stomach now, but to relieve pain and restrain the diarrhoea and tenesmus we gave him an enema of a drachm of tincture of opium and one of starch. This relieved these symptoms and the cramps in the legs. He was given albumin water by the mouth during the rest of the night, and then milk and barley water. There was only one motion of the bowels, and this not until late in the evening. When next seen, about 10 a.m., the temperature was normal, and the pulse 100. He was very restless, and complained of fidgets in the legs but no cramps. The conjunctivae of both eyes were slightly congested. No urine was secreted; a rubber catheter was passed, but no urine was found in the bladder. He was then seen by Dr. H. McKisack, and diuretics were ordered, with mustard and linseed poultices to the loins in order to encourage the action of the kidneys and assist in the elimination of the poison. Magnesium sulphate was also given freely. This had the desired effect, and urine was freely passed. The patient was now able to be up and about, and soon was walking in his garden; eventually he even walked down to my house.

The first untoward symptom that showed itself was a feeling of pain in both arms and forearms which he compared to neuralgia, for which he was given phenacetin and aspirin, with massage. This increased to a feeling of numbness in the parts supplied by the radial nerves of both hands, so that he was unable to hold a cup or spoon firmly, but he was still able to walk. Dr. McKisack, who again saw him with me, suggested in addition to the potassium iodide which he was now taking, and the massage, that he should have a continuous current applied, and for this reason he was removed to a nursing home in Belfast on April 30th. He was then able to walk, but said his feet felt as if he were walking on wool. Very soon after he was brought there he was found to be ataxic in his gait; he was unable to stand upright if his eyes were closed, or to make an attempt to walk if his eyes were closed without falling. The knee-jerks gradually became lost and ankle clonus appeared. He became slowly but steadily worse, hypostatic pneumonia developed, and death took place on June 13th by slowly ascending paralysis. Up to the end arsenic could be found in the urine.

GEORGE ST. GEORGE, M.R.C.P.I., L.R.C.S. Edin.,
Surgeon, County Antrim Infirmary, Lisburn.

A TUMOUR OF THE NECK.

THE following case may be of interest, especially from a diagnostic point of view:

Mrs. W. was admitted to the Wakefield Hospital in March, 1920. For five years she had suffered from an enlarged tonsil (right). At intervals she had acute attacks accompanied by pain and increased difficulty in swallowing, which subsided after the discharge of pus. It was ascertained afterwards that the pus came, not from the tonsil, but from the ear. Recently the tonsil had become larger, and the swelling appeared under the lobule of the ear, and another in the submaxillary region.

On examination, there was a swelling about the size of a chestnut just below the lobule of the ear, which seemed to fluctuate. There was another similar swelling in the submaxillary region. The mouth could be opened easily, and the so-called enlarged tonsil was seen to project from between the pillars of the fauces and extend across the pharynx, leaving only a small space on the left side for the passage of food. The mucous membrane covering it was of normal colour, and palpation of it caused no discomfort.

A curvilinear incision was made behind the angle of the jaw, revealing almost immediately a solid tumour which proved to be the size of a duck's egg, and of similar shape, except where an outgrowth, softer than the rest of the tumour, passed outwards towards the lobule of the ear. The tumour was shelled out with ease, save perhaps where various seekers after pus had pursued their rigorous

investigations. On the outer pole was the attenuated submaxillary gland, and on the inner a trophic tonsil. Microscopic examination of the tumour showed the presence of fibrous tissue, cartilage, muscle, fat, and some epithelial elements. Recovery was uneventful.

ADVANCING YEARS AND BALNEOTHERAPY.

SENESCENCE in general and from the balneotherapist's point of view was the subject of Dr. G. L. PARDINGTON'S presidential address delivered to the Section of Balneology and Climatology of the Royal Society of Medicine on January 27th. After a concise survey of the atrophic and degenerative changes which made their appearance with advancing years, he said that for the maintenance of physiological equilibrium and the prevention of functional failure, or its anticipation and the limitation of its effects, reliance must be placed on hygiene in the widest sense, including regulation of diet, methods of living, work, rest, and exercise. It was here that balneotherapy found one of its most effective uses. Balneotherapy he defined as the application to the body surface of thermal and mechanical stimuli by means of water, air, or rays of incandescent light; the effects of such stimuli varied with the temperature, duration of application, area involved, technique, and condition of the patient. The first four of these factors were under the physician's control, and the fifth called for his careful supervision.

The temperature of the skin, Dr. Pardington continued, averaged about 90° F., which point formed the zero of thermal stimulation. It might be that the effects of stimuli within the range from 78° to 98° differed specifically as well as thermally from those beyond either extreme. The duration of any balneotherapeutic procedure should vary inversely with the intensity of the thermo-stimulation, and this applied especially to the lower ranges of temperature. A few seconds would suffice for decidedly cold or hot applications, except in local measures such as douches, where mechanical effects were superadded. The duration of moderately hot or cold applications might be measured in minutes, while the neutral bath (95°) might be employed for half an hour for a general sedative effect. Generally speaking, those cutaneous areas which had the best vascular supply yielded the best response to cold applications. Precision in details of administration influenced very largely the attainment of the desired result. The bath chamber should be well ventilated and warmed to 75°. In measures involving percussion and vibration it was important that the force of water should be adequate—some 20 or 30 lb. to the square inch. A careful estimate should be made of the condition of the patient, more especially with reference to the cardio-vascular apparatus, the blood pressure, the possible existence of anaemia, and the state of lungs, kidneys, and excretory organs. Individual predisposition as well as age had to be considered.

Dr. Pardington then discussed indications and results. The effect of a cold general application was a contraction of the peripheral vessels of the skin and a general reduction in surface temperature. The effect on the peripheral terminations of the sensory nerves resulted in a powerful stimulation of the central nervous system. The respiratory centre was very largely stimulated, and the respirations after the initial shock were temporarily quickened. The pulse was also quickened and the blood pressure raised. Afterwards the reaction occurred, and the feeling of chilliness was succeeded by warmth and exhilaration. This was the expression of physiological resistance, and its complete attainment was the object to be aimed at in all general tonic measures. It was necessary to be alive to the possibility of untoward results, such as deficient reaction, indicated by pallor, coldness of skin and extremities, faintness, and giddiness, which called for hot drink and warm clothing; and excessive reaction, shown by over-excitation of the heart, throbbing headache, and profuse sweating, which might be met by a general cold application (from 80° to 65°). Such untoward reactions might be encountered immediately, but there were other manifestations more remote, such as

excessive tissue change, indicated by loss of weight strength, and appetite, and by dyspnoea, which was generally due to some overlooked asthmatic affection. Cold tonic measures were usually best for the disordered metabolism which was often the initial phase in the disturbed conditions observed in advancing years, but such applications must be carefully graduated. The needle bath was one of the most useful means of treatment, as it could be regulated in temperature and duration with the utmost nicety. Where there was any tendency to cardiovascular change extremes of all kinds were to be specially avoided, and tentative procedure was called for. Phlegmatic persons tolerated very well douches under suitable pressure. The sedentary were benefited by sudoriparous measures as well as by cold tonic treatment. The painful and stiff joints due to senile changes were much benefited by heat packs followed by cold douches. Turkish and Russian baths, especially the latter, were unsuitable in advancing years, particularly in the case of those unaccustomed to them, and all the advantages of such measures could be got equally well by hot air or vapour cabinet baths, or, better still, electric light cabinet baths. Baths of indifferent temperature (95°) were of special importance in senescence, especially in conditions of nerve irritability and insomnia, provided that reaction was carefully guarded against.

Dr. Pardington said, in conclusion, that he had been brought into contact with many people well advanced in years, some of them quite old, who had impressed him by their unusual vitality. They were people who had availed themselves regularly of a balneological course of treatment. Their vigour and alertness both of body and mind might be attributed to a lifelong observance of all the physiological commandments, but he knew that in the case of some of them this was not so, and he had been forced to the conclusion that balneology explained to a large extent their high standard of health. It was the case of these valetudinarian veterans which had suggested the theme of his address.

TESTICULAR DISEASE FOLLOWING TRACMA.

At a meeting of the Medico-Chirurgical Society of Edinburgh on January 19th, Emeritus Professor F. M. CAIRD presiding, Mr. CHARLES W. CATHCART read a paper on epididymitis and orchitis from muscular strain, followed by tuberculosis of the epididymis. The problem was twofold: First, could a severe muscular strain of the abdominal wall set up acute epididymitis and orchitis; and secondly, could this acute inflammation excite sub-acute tuberculosis of the affected parts? The following case from his own experience was typical, and was both of surgical and medico-legal interest.

A young miner, aged 21, and previously in perfect health, strained himself in attempting to lift a heavy weight. At once there was sharp pain in the lower abdomen on the left side, and very soon a "gripping" pain in the left testicle, associated later with nausea. He then noticed himself that the scrotum was swollen and reddened, and this was confirmed by his doctor a few hours later. Some days later the left testicle was found to be swollen and tender, this subsiding in a few days. But two weeks later pain returned very severely, swelling increased, and after a month an abscess was incised, which was found to be due to a tuberculous epididymis (left).

Mr. Cathcart reviewed fourteen similar cases from the literature and from private records. In some of these there was passage of blood per urethram; but in most this was absent. The effects on testicle and epididymis varied—in some a transient swelling, in others subsequent atrophy or chronic inflammation. It seemed clear that a simple muscular strain could produce such injuries, and that they were analogous to the strains and ruptures of ligaments and muscles, and to the sudden hernias of healthy people. As to the mechanism of production of the lesion there were two theories. Hilton's view was that there was a rupture of the vas deferens; while the view of Barthélemy and others was that torsion of the vas took place, and this could account for all the symptoms, including that of urethral bleeding. The speaker on the whole favoured the "torsion" theory in the majority of such cases. In Lapointe's 34 cases of torsion of the vas deferens there was no history of trauma or effort in 6; while in 19 there was some strong sudden contraction of the abdominal muscles. The variation in the symptoms as to rapidity of

Dr. JOHNSTON recorded the case of a woman who had a Pott's

fracture reduced under nitrous oxide, and who died ten minutes after recovery from the anaesthetic. On post-mortem examination there was thrombosis in the femoral artery and vein of the affected limb, and an embolus in the pulmonary artery.

THE annual meeting of the North of England Obstetrical and Gynaecological Society was held at Manchester on January 21st. Mr. CARLTON OLDRIELO (Leeds) was elected President for the ensuing year. Dr. BRIGGS (Liverpool) showed a specimen of tuberculous salpingitis removed from a patient thirteen years previously; she was now in perfect health. He was of opinion that inflamed tubes were more commonly tuberculous than was usually supposed. Dr. W. W. KING (Sheffield) showed a specimen of hydrometra removed from a nulliparous patient. The uterus was the size of a four months pregnancy and the obstruction to the outlet of uterine secretions was caused by a small cyst arising in the mucosa of the cervical canal. Dr. CLIFFORD (Manchester) showed a large ovarian tumour removed from a girl aged 12 years. The growth was a sarcoma of rapid growth with extensive areas of necrosis. Dr. SHAW (Manchester) described a case where he had removed a large myxomatous tumour of the left ovary, the other ovary being at the time apparently quite healthy. Twelve months later the patient returned with a large abdominal tumour which, at operation, proved to be a similar growth of the right ovary. Dr. LACEY (Manchester) read a paper on induction of labour for contracted pelvis, based on a series of 75 cases, in which the conjugata vera measured not less than $3\frac{1}{2}$ in. in flat nor $3\frac{1}{2}$ in. in generally contracted pelvis. The method adopted was that of Krane, but this was instances by the introduction of a bag. The maternal mortality was morbidly 1.3 per cent.; 84 per cent. of the children were born alive, and of these, 78.6 were discharged well on or about the twelfth day.

Reviews.

GROWTH AND SHEDDING OF ANTLERS.

IN his beautifully illustrated monograph on *The Growth and Shedding of the Antler of the Deer*, which describes in detail the histological phenomena and their relation to the growth of bone, Sir WILLIAM MACWEN,¹ Regius Professor of Surgery in the University of Glasgow, presents us with a full account of the results of a prolonged inquiry. He was no doubt attracted to this subject by his well known interest in the development of bone, and further light is thrown on this problem. The quantity of osseous matter secreted annually to form the antlers of the larger deer is enormous, and was stated by the late Sir William Flower to have been in certain instances more than that of all the bones of the skeleton put together. As the growth of the antler proceeds from a single comparatively small centre of ossification in the frontal bone, the cellular proliferation is in excess of that seen not only in any normal process, but also in the most rapidly growing tumours. The growth of the antler is in some respects analogous to that of bone which follows amputation through the arm or thigh of a child, ultimately forming a conical stump as a result of continuous proliferation at the proximal epiphysis; but the antler has a tip of actively proliferating cartilage, and is covered by the velvet—a remarkably complete reproduction of the skin with its glands, nerves, vessels, hair follicles, and appendages.

The evolution of the osteoblast is illustrated by most successful photomicrographs, and the syncytium, from which bone and cartilage develop, is shown to be alike in the antler of the deer, in bone grown experimentally in glass tubes, in dog's bone, in human growth, and in the regeneration of bone, such as in repair after osteomyelitis and in the healing of fractures. The separation of the antler depends primarily on the withdrawal of its blood supply and is an aseptic process. The concluding chapter is devoted to the phenomenon of nuclear budding observed in osteoblasts that have reached or are approaching their mature form; since it has been seen in deer's antlers it has been detected near the growing epiphyses in the dog and in man, as well as in morbid processes attended by rapid growth, such as sarcoma. The check to the growth

of the antler produced by castration probably involves among other changes, cessation of nuclear budding.

When regarded from the evolutionary point of view the stag's antlers are a great puzzle. It is not easy to see that they serve any purpose which, even if they grew once for all, would be commensurate to the expenditure of energy and material; as the antlers are shed annually the puzzle becomes greater. So far as we are aware there is nothing comparable in nature. We have dwelt upon the histological side of Sir William Macwen's book, but it will interest all those concerned in natural history, whether as naturalists or sportsmen.

A FRENCH SYSTEM OF MEDICINE.

A new treatise on medicine,² produced under the distinguished editorship of Professors ROGER, VIDAL, and TEISSIER, promises to constitute a landmark in the annals of the medical literature not only of France, but of the world in general. The list of collaborators whose services have been secured to contribute to this great system of medicine includes all those living Frenchmen whose work and opinions we hold in highest esteem.

In 1891 the classical system of Charcot, Bouchard, and Brissard appeared, and presented a wonderful collection of monographs and original memoirs on the whole domain of medicine. About 1912 Bouchard considered the time had come for a new edition or rather a new treatise. He turned therefore to his old pupils Roger, Vidal, and Teissier, to undertake the direction of the new work, which was to embody as far as possible the whole contributions of modern France to medical progress. It is difficult to realize fully how extensive and important those contributions have been during recent years, but on reading through the list of contributors to the new treatise we do at least recognize that nearly all the names sound as familiar and famous in England as in their own country.

The treatise is to consist of twenty-one parts or fasciculi, each of which will be almost a complete book in itself on some branch of medicine.

The first fasciculus is one of three, or, more correctly, of five, which are to deal with infectious diseases and diseases due to parasites. Roger introduces the subject with a section on infection in a general sense. He classifies and describes the various infective agents, giving brief accounts of the biological characters and their effects in man and in animals. We say particularly "and in animals" because it is evident that France enjoys a peculiar heritage from the work of Pasteur—namely, that the study of comparative medicine is regarded as part and parcel of the study of disease in man; whereby the health of man and animals alike will, we believe, profit incalculably. Other subjects dealt with in the first fasciculus are septicaemias by E. Saquépée, streptococcal infections by Roger, pneumococcal infections and pneumonia by Menétrier and Stévenin, and infections from staphylococcus, tetragera, enterococcus, Pfeiffer's bacillus, and Friedländer's bacillus, as well as psittacosis and proteus infections by H. Macaigne. A. Veillon writes on putrid and gangrenous infections, Dopter on the meningococcus, and Hadelo on gonococcal infections.

This book is particularly welcome because it sets once and for all an example of the way to combine in a single description the pathologist's and the clinician's view of a disease. This is admirably illustrated in Dopter's account of meningococcal infections. French medicine is to be envied for this capacity of either making physicians pathologists or keeping pathologists still physicians. No small part of the credit for this is due to Pasteur and to the Pasteur Institute, which discovered the secret of attracting such men as Metchnikoff, Daculx, Roux, and Calmette.

This we believe to be the influence which is inspiring medicine in France at the present day and giving it its undoubted eminence. It would be hard to equal, from a the world beside, a list of contemporary pioneers in medicine like theirs, which includes Richet and Portier with their work on anaphylaxis, Bordet and Gengou on agglutination, Vidal on cytodiagnosis, Pierre Marie, who first described acromegaly and has added much else to our knowledge of nervous diseases; Babinski, Chaffard,

¹ *The Growth and Shedding of the Antler of the Deer*. By Sir William Macwen, F.R.S. Glasgow: MacLehose, Jackson and Co. 1920. (Demy 8vo, pp. 125; 103 figures, 10s. 6d. net.)

² *Nouveau Traité de Médecine*. Fascicule I, Maladies Infectieuses. Editors: Professors Roger, Vidal, and Teissier. Paris: Masson et Cie. 1920. (Sup. roy. 8vo, pp. 439; illustrated. Fr. 35 net.)

Marcel Labbé—when one begins one scarcely knows where to stop, name after name comes back to the memory. The *Nouveau Traité de Médecine* is intended to give us the whole wealth of learning of which contemporary France is capable. From the first volume we have gained such a feeling as gives us the keenest appetite for the rest. The publishers, Masson of Paris, have spared neither expense, pains, nor art to produce a work which, by its typography and its illustrations, may be held worthy of its subject matter.

PREVENTION OF DISEASE IN THE TROPICS.

DR. ANDREW BALFOUR'S volume, *War Against Tropical Disease*, contains seven papers, all of which, with one exception, have previously appeared in periodical publications. Dr. Balfour is well known as a pioneer worker in tropical medicine and hygiene, and the object he has had in compiling this volume may be gathered from the fact that he has called his papers "sermons," because, he says, "they are intended to spread that gospel of hygiene which is so important both at home and abroad."

All successful efforts at evangelization must be clothed in plain language, and, in this sense, the author has succeeded in being an evangelist. True to this mission, he insists on the fundamental truths of hygiene rather than entering upon a discussion of modern doctrine. To say, therefore, that the book contains little that is not already known to the expert, is to pay a compliment. Those who read the book will appreciate this, and from the many apt references and quotations will feel that Dr. Balfour's gain to the profession is an obvious loss to "the cloth."

The papers deal with sanitation and preventive medicine in various parts of the tropics, both in the old and the new worlds, as well during the war as in peace time. Stress is rightly paid to the importance of insects as carriers of disease, and in the paper on the "Medical Entomology of Salonica" a useful account is given of the anatomy and distinguishing features of the various kinds of insects concerned. In giving an account of the "Preventive Inoculation against Typhoid and Cholera" the difficult problem of immunity is dealt with in a popular and lucid manner.

"The Palm from a Sanitary Standpoint" has been specially written for this volume and has not appeared in print before. The effect of palms on mentality, their domestic and economic uses, their employment as breeding places by mosquitos and other insects, are among the subjects dealt with and give interesting reading.

The book should prove of considerable value to anyone, medical or lay, proceeding to or living in the tropics, and even those whose life is spent at home will find much to interest them and help the spread of the gospel of hygiene at home as well as abroad. The book is well produced and is illustrated with many admirable photographs.

THE INVOLUNTARY NERVOUS SYSTEM.

In this little book on the sympathetic and associated systems, to which Professor PIERRE MARIE contributes an introduction, M. GUILLAUME, who is already known to British readers by his studies on the neurological injuries and diseases of war, has produced a short account of the involuntary nervous system, dealing with its anatomy, physiology, and pathology, as well as with its clinical aspects. The nomenclature of the subject is confused, and a general agreement about it is urgently needed. British readers, following Gaskell, would prefer the term "Involuntary Nervous System," dividing this into sympathetic proper and parasympathetic. A brief introduction is followed by chapters on the morphology, anatomy, and physiology; they are concise and well illustrated by simple and clear figures in the text and the physiological and anatomical connexions of the cranial nerves are well described. The clinical pictures produced by injury or disease are given in considerable detail. Perhaps the author is a little too dogmatic in some

of his statements here, and he might have qualified his conclusions somewhat—for example, as to the effect of lesions of the cervical sympathetic. A useful chapter is one on the action of drugs upon the involuntary nervous system.

The vexed subjects of vagotonia and sympathicotonia receive full consideration in later chapters, where the views of Eppinger, Hess, and others are discussed. The author prefers the term *neurotonia* to *vagotonia*, believing that this picture is dependent on increased action of the sympathetic proper as well as of the parasympathetic system. Referred pains and the various visceromotor and sensory reflexes form the subject of another chapter.

The style is easy and the book is pleasant to read; the author may be congratulated on having compressed so much information into so small a space without sacrificing the clinical interests of the subject. We do not find any new material, but the book as a whole constitutes a good review of our present knowledge of this difficult subject.

SYPHILIS IN THE TROPICS.

Those who are accustomed to see eruptions on the skin of Europeans are often puzzled when confronted with similar conditions in dark-skinned races. The book on *Syphilis, with Special Reference to the Tropics*, by Mr. K. K. CHATTERJI, F.R.C.S.I., will help to lessen this difficulty in respect to the lesions of syphilis, as his material is largely drawn from the peoples of India. Chapter XI deals specifically with the tropical aspects of this disease; we wish it were longer. It is important, for example, to know that 96 per cent. of undiagnosed tropical ulcers give a positive Wassermann reaction.

The author has a high opinion of the therapeutic properties of margosa oil, obtained from the margosa or nim tree which abounds in all parts of India; from early times its healing powers have had a high reputation. The mode of preparation of margosic acid and its salts was described in the *Indian Journal of Medical Research*, April, 1918, p. 656. The drug is given by intravenous or intramuscular injection, and arsenic, mercury, and other salts are used. As further investigations are in progress it would be premature from the information in our possession to express any opinion as to the value of the drug.

The book is evidently the outcome of much care and labour, and a good deal of technical information has been incorporated in it. Some of the illustrations are lacking in clearness, and at times fail to convey a precise idea of the eruptions they represent, but no doubt this defect may be attributed to the difficulties of the present time, and will be corrected in future editions. There is an excellent bibliography of recent work, and the indexing has been done in an admirable manner. We believe the book will prove useful to those for whom it is intended—namely, to practitioners in the tropics.

TWO MEDICAL POETS.

DR. DAVID RORIE of Culter is well known as a poet of the vernacular to his Aberdeenshire friends, and doubtless many who served with him in the war, where he was A.D.M.S. of the 51st Highland Division, receiving the D.S.O., and being named Chevalier de la Légion d'Honneur, made the same discovery.

When the sharpest flint made the deepest dint,
An' the strongest worked his will,
He drew his tune frae the burnie's croon
An' the whistlin' win' o' the hill.

Like "the man o' the cave," Dr. David Rorie draws his inspiration from "hameowre" (homely) themes. The poems are the musings of a country doctor. His Rorie has the sturdy lilt of Aberdeenshire, though here and there a note of Fife is heard. He who loves the Doric and a laugh should read *The Auld Doctor*. The themes are typical, and the humour sure and human. Two of the poems appeared in *The British Students' Song Book*, "The Lum Hat wantin' the Croon," and "The Pawky

War Against Tropical Disease. Being Seven Sanitary Sermons addressed to all interested in Tropical Hygiene and Administration. By Andrew Balfour, C.B., C.M.G., M.D., etc. Published for the Wellcome Bureau of Scientific Research by Messrs. Baillière, Tindall, and Cox. 1920. (Cr. 8vo, pp. 180; 2 maps. 12s. 6d. net.)

Le Sympathique et les Symplicites Associées. By A. C. Guillaume. Preface by Professor Pierre Marie. Paris: Masson et Cie. 1920. (Cr. 8vo, pp. 150; 21 figures. Fr. 6.50 net.)

Syphilis in General Practice; with Special Reference to the Tropics. By K. K. Chatterji, F.R.C.S.I. With an introduction by W. D. M.S. Calcutta and London: Butterworth & Co. 1920. 382; 56 plates. 15s. net.

Other Poems and Songs in Scots. By David Rorie, M.D. London: Constable and Co., Ltd. 1920. (Crown 8vo, pp. 61. 3s. 6d. net.)

Duke." As an expression of the concrete, nothing can be better than—

The burn was big wi' spate,
An' there cam' tum'lin' doon
Tapsalteerie the half o' a gate.
Wi' an auld fish-lake an' a great muckle skate,
An' a lum hat wantin' the croon!

"The Pawky Duke," like the origin of Rorie's ballad of "Macfadden and Macfee," shows the pawky author with his tongue in his cheek:

An' if he met a Sassenach,
A-tour in Caledonia,
He gart him lilt in a cotton kilt
Till he took an acnte pneumonia!
Hech mon! The pawky duke!
He'at a Sassenach wi' pneumonia!
He lat him feel that the Land o' the Leat
'S nae far frae Caledonia!

Every poem tells its story, from the complaining wife that

had some unco queer mishaps.
Wi' nervish wind and clean collapse,
An' naethin' does her guid but draps—
Guid draps o' barley-bree, O!

to the obese Mistress Mucklewame, diagnosed by a "speeshalist" as suffering from "ang-bang-pang." The longest poem and the most amusing is "Tam and the Leeches," in which medical humour is given full scope and the druggist shop is depicted with the eye of a Hogarth. In its general plan "Tam and the Leeches" is reminiscent of "Tam o' Shanter."

Dr. C. J. WHITBY belongs to an altogether different school. For him life is full of seriousness and his mind and ear are sensitive to every modern movement. He has collected poems written at various dates, and for the most part published in earlier volumes or periodicals, into a book entitled *The Rising Tide*.⁷ It consists of three parts, the first comprising poems written during the war or the years immediately preceding it, the second containing miscellaneous poems of earlier date, and the third two episodes from an unfinished epic, "The Deeds of King Olaf." The poem which gives its name to the volume, like several others in the first part, is in irregular unrhymed verse. Dr. Whitby, in a foreword, says that it is "strange that the universally significant, the pre-eminently poetic topic of childbirth should so generally have been overlooked or neglected." Though the realism of the writing is strong it is free from offence, and the poem may be compared, not to Dr. Whitby's disadvantage, with Zola's famous prose description. Among the earlier poems we find some agreeably turned verses entitled "On Leaving Limpley Stoke." Among the recent poems in more regular measure we would give high place to "Salutation," addressed to the first Canadian Contingent. From it we may quote the concluding stanza:

Canada, Canada!
Transient are the losses and the pains
But the splendour of the deed remains.

Generations yet unborn shall tell
How the brave Canadians fought and fell.

Pride with grief contends in me; for one
Called me father. Sleep'st thou well, my son?

NOTES ON BOOKS.

THE fortieth volume of the *Transactions of the Edinburgh Obstetrical Society*⁸ embraces the proceedings of the society during the session 1919-20. The meetings were suspended during the war, and this is the first volume that has appeared since the session 1913-14. The contents include Sir Halliday Croom's valedictory presidential address, and papers by Dr. Lamond Lackie on artificial rotation of the head in persistent occipito-posterior positions; by Dr. Francis Browne on the histology of hydatidiform mole in its relation to prognosis; by Dr. Berry Hart on persistence of puerperal septicæmia since the end of pre-antiseptic times; by Dr. Robert Robertson on vaccine therapy in gynaecology and obstetrics; by Dr. J. W. Ballantyne and Dr. F. J. Browne on the colour scheme in pregnancy; by Professor Jardine and Dr. A. M. Kennedy on suppression of urine in pregnancy

⁷ *The Rising Tide, and Other Poems*. By Charles Whitby, B.A., M.D. Caithness. London: E. J. Matthews. 1920. (Demy 8vo. pp. 112. Price 5s. net.)

⁸ 1920. Edinburgh: Oliver and Boyd.

and the puerperium; and by Dr. Eardley Holland on cranial stress in the foetus during labour. The volume is well printed and well illustrated.

India has contributed many useful articles to the *materia medica*, but in addition to those that have found their way into the *Pharmacopœia*, there are many drugs sold in Indian bazaars and used by native *vaidas*, *Kavirajs*, and *hakems* which are very sparingly employed by European doctors or stocked in Indian hospitals and dispensaries. Books have been written on indigenous Indian drugs by Webb, Kanve Lall Dey, Mooden Sherrif, and others, but it is doubtful whether they have succeeded in introducing these drugs into practice to any considerable extent. Lieut.-Colonel G. T. BIRDWOOD, of the Indian Medical Service, has written a book⁹ the purpose of which is to commend and facilitate their use, more particularly in district and mission dispensaries. The book sets forth (1) a list of bazaar medicines according to their action as alteratives, anthelmintics, etc.; (2) a description of these, indicating alphabetically their source, action and method of use; and (3) an alphabetical list of diseases in the treatment of which various bazaar drugs may be usefully employed. Over two hundred prescriptions are given suggesting the best methods of their administration. As a practical guide to the use of these medicaments this handy volume leaves little to be desired. The book is well printed and bound, interleaved for notes, and carefully indexed. It is to be hoped that it will not only help to commend indigenous medicines to the notice of Indian medical men, but will lead to research into their therapeutic value.

CALENDARS.

The *Calendar of the National University of Ireland*¹⁰ gives complete information about that university and its three constituent colleges—University College, Dublin; University College, Cork; University College, Galway—and includes extracts from the regulations for courses in the Faculty of Medicine.

The current *Calendar of University College, University of London*¹¹ forms a comprehensive guide book to the courses, examinations, scholarships, and so forth in the various faculties; it is prefaced by the historical outline written by the late Dr. Carey Foster.

A much smaller volume, but one that has a certain general interest in view of the forthcoming Annual Meeting at Newcastle, is the *Calendar of the University of Durham College of Medicine*.¹² Founded in 1832 as the Newcastle-upon-Tyne School of Medicine and Surgery, this medical school became associated twenty years later with the University of Durham, and when, in 1870, this connexion was knit closer, it received its present name.

⁹ *Practical Bazaar Medicines*. By G. T. Birdwood, M.A., M.D. Cantab., Lieutenant-Colonel I.M.S., Civil Surgeon, Lucknow. Calcutta and Simla: Thacker, Spink, and Co. 1920. (Fcap. 8vo. pp. 125. Rs. 3.8 as.)

¹⁰ Dublin: Printed for the National University by Alex. Thom and Co., Ltd. 1920.

¹¹ London: Taylor and Francis. 1920.

¹² Newcastle-upon-Tyne: Andrew Reid and Co., Ltd. 1920.

APPLIANCES AND PREPARATIONS.

A Device to Assist in the Introduction of a Pelvic Drain. SIR W. I. DE C. WHEELER, Vice-President, Royal College of Surgeons, Ireland, writes: The thimble illustrated is of great assistance in making a suprapubic opening for drainage in cases of septic peritonitis. The primary incision, when the case is one of perforation of the stomach, duodenum, or appendix, is usually at a distance from the pubic region. A pelvic drain in most cases is desirable. At the end of the operation, before the primary wound is closed, the finger guarded with the thimble is introduced into the abdomen and seeks the interval between the recti muscles just above the pubes. At this point the space between the muscles is well marked. With the thimble as a guide a stab wound is rapidly made, dividing all the tissues down to the peritoneum. The latter is pushed forward and is opened by a nick of a sharp-pointed knife between the bars carrying the round knob. A drainage tube (Keith's glass tube for preference) is fitted to the top of the thimble

and is guided with great ease to the bottom of Douglas's pouch. The device saves time and overcomes the real difficulty of opening the peritoneum through a small incision. If the ungarded finger is used as a guide, the peritoneum stretches itself over the rubber glove and it is troublesome to separate one from the other. Surgeons must avoid cutting too boldly on an ungarded finger in the presence of septic peritonitis.

THE VOLUNTARY PRINCIPLE IN LONDON.

A MEETING of the President and General Council of King Edward's Hospital Fund for London on January 26th received a report from the Executive Committee, which had been instructed to consider what principles of policy should be recommended to the Government for the preservation of the voluntary system of hospital management and control. The general recommendations of the Executive Committee were adopted as follows:

1. That the voluntary system of hospital management and control should be preserved as being the most efficient method of providing at the least cost the best medical and surgical treatment combined with advance in medical knowledge and practice;
2. That a substantial portion at least of the cost of the hospitals should be met by voluntary contributions;
3. That the present receipts from voluntary contributions are not adequate to meet the present cost of the London voluntary hospitals, to say nothing of the discharge of debts or the provision of necessary extensions;
4. That any method of increasing income should be such as not to stop voluntary contributions or do away with voluntary management;
5. That any policy or absence of policy which stopped voluntary contributions and did away with voluntary management would bring upon the public funds not only the cost of the hospitals but also additional cost of paid management and of general supervision by some central public department.

So far as could be ascertained, so soon after the conclusion of the year, the total expenditure of the London hospitals in 1920 was £2,841,000; this was £493,000 more than in 1919. The income from normal sources, including the ordinary grant from the King's Fund, was, in 1920, £2,447,000, leaving a deficit of £394,000; by an emergency grant of a quarter of a million made by the King's Fund on July 5th this deficit was reduced to £144,000. The aggregate debt of London hospitals, after deducting £200,000 given last December by the National Relief Fund towards the reduction of past deficiencies, was £544,000 (£138,000 less than in the previous year). Besides the amount required to meet current expenses and to discharge existing debts the hospitals in London also need a large sum to carry out and maintain various necessary improvements and extensions. Among these extensions is provision for approximately 1,500 additional beds.

It is considered that were the uncertainties as to the future of voluntary hospitals removed appeals for contributions would be more successful, but even so it would be necessary to supplement them by some other source of revenue. The possible methods, as to which experience is being accumulated, and of which exploration should be encouraged, include:

- (a) Various forms of contributions from patients in consideration of treatment received;
- (b) Various forms of regular contributions from prospective patients as a kind of quasi-insurance whereby a patient who has directly or indirectly been a regular subscriber should be regarded as having partly made a patient's payment in advance. Experiments in this direction might be encouraged.
- (c) Payment by Government or other public authorities in respect of the treatment of any classes of patients for whom those authorities have taken responsibility.

The opinion is expressed "that, while direct grants from the State in consideration of their general work might endanger voluntary contributions and voluntary management, some form of assistance based on the amount received for the benefit of hospitals from voluntary sources, or some concession by way of abatement of income tax or some duties, proportioned to gifts, might prove practicable, and might serve to elicit a larger revenue than is now thus obtained."

It is pointed out that for many years past many hospitals have in fact been receiving payment from public authorities; besides naval and military patients treated during the war, payments have been received for tuberculous patients, venereal cases, war pensioners, maternity cases, school children, and others; the payment has usually been a grant-in-aid bearing some relation to the amount of work done, but not covering the whole cost. It is considered that the method has proved advantageous. The Council of the Fund proposes to obtain the view of the individual hospitals in London and also of the British Hospitals Association on the question of payment in respect of the great volume of gratuitous work which the voluntary hospitals do for patients insured under the National Insurance Act.

While the need for increased income is great, it is held that attention should continue to be paid to the possibility of further economies in expenditure by strengthening the internal financial control of each hospital, by encouraging co-operation among the hospitals, and by securing that the best possible use is made of the various forms of voluntary accommodation and equipment. Upon this last point the report says:

It is clear that as the demand for hospital treatment grows, the voluntary hospital system must either expand so as to meet the whole of that demand itself; or submit to the establishment of other agencies to compete with it in the attempt to meet the whole of the need; or confine itself to meeting the whole of the increase in the particular kind of demand which it may be best fitted to meet. Different decisions between these three courses may be appropriate to different localities or to different kinds of hospital. But correct decisions there must be, if the voluntary hospital is to keep its proper place in the growing medical service of the country.

The voluntary hospitals of London have already prepared, with the sanction and encouragement of the King's Fund, plans for extensions to meet the most urgent need for further accommodation of the kind they are most fitted to supply. The report of the Distribution Committee in July last, at the time of the special distribution of surplus Red Cross funds in aid of schemes of extension and improvement, gave statistics of approximately 1,500 additional beds, which the Fund had already sanctioned, after paying due regard to the class of hospital and to the geographical distribution of the schemes in relation to the demand, and subject to the Hospital Committee being satisfied as to the prospect of funds for building and maintenance. This last condition assumes, of course, some solution of the general financial problem.

On the question whether the voluntary hospitals should attempt to cover the whole ground, and oppose all other methods of providing hospital accommodation, no recommendation is made, but the report contains the following observations:

We would remark that the present sphere of the voluntary hospital is the result of a process of specialization by which various sections of the increasing demand for hospital treatment have been taken over by other agencies, though the voluntary hospital still performs for those agencies, as for its ordinary patients, the services for which it is best fitted, including consultative work and the advancement of medical knowledge. We would mention the Poor Law infirmary and the public fever hospital as two instances. It is possible and the best use of the voluntary hospital accommodation and that the best use of this principle of partial specialization, further development of this principle of partial specialization, either, for example, between one voluntary hospital and another, or between a parent hospital and branches such as homes of recovery and convalescent homes, or even, as in the instances mentioned above, between the voluntary hospital and the non-voluntary hospital.

It is pointed out that any policy which may be adopted must provide not only for current expenditure and reduction of debt but for such extensions of the voluntary hospital system as is urgently needed.

A central body will, it is considered, be a necessary part of hospital organization. In the case of hospitals in London this, it is thought, could best be provided by a development of the present functions of King Edward's Hospital Fund, which might become the central administrative body for the metropolitan area. The administrative body of the extra-metropolitan hospitals should be separate, but for the formulation of general policy a joint body, composed of members of both, should be formed, and be independent of any Government department or other public authority. If the King's Fund became the central administrative body for the hospitals in London it would continue to investigate hospital finance and administration, to promote economies, to examine extension schemes, and to receive voluntary contributions, but it could likewise provide a channel for the receipt and distribution of some form of public assistance, should that be determined on, either in a permanent or in a temporary form. The Council of the Fund is, however, clear that individual hospitals should continue to be under the management of unpaid voluntary committees with fairly wide powers of discretion and initiative. The receipt of payment from public authorities has not hitherto led to any material change in this respect, and it is hoped that the advantages of the voluntary system would continue to be so generally recognized that public or other bodies making payments to the hospital would, if they desired representation, be satisfied that it should be so limited as to be acceptable to the hospitals and not inconsistent in practice with voluntary management.

THE RECORD CARD AS EVIDENCE.

BY A LEGAL CONTRIBUTOR.

MUCH has been written in the daily papers about "Record Cards." Some journals seem desirous of creating an impression that by reason of the publicity of the record card the secret of the consulting-room is to be no longer a secret; while others apparently assume that a record card becomes and remains a document which at all times and in all circumstances may be put in evidence either for or against the person with whom it deals.

In view of the fact that laymen do not always understand the law of evidence, it may be interesting to discuss the following question: "How far is an insurance medical record card evidence in a court of justice?"

It may be stated at once that it is not what the lawyers term a "privileged" document. This is for the simple reason that there is no such thing as medical professional privilege. A doctor is bound to state on oath in the witness box all he knows about his patient. This rule is well known and well recognized; but the writer has been unable to find the report of any case in which a doctor has been punished for its infraction.

Dr. Bateman,¹ indeed, recorded one case in which, on a summons by a married woman for arrears of maintenance, a medical practitioner was subpoenaed by the husband's solicitors. On being sworn, he was asked if he had not attended the woman professionally on a certain date, she being in labour. He declined to answer, claiming privilege. The Bench pointed out that such privilege did not obtain, and as he again refused they adjourned the case for a week in order to allow him to reconsider his position. He still refused when the court sat again, and the Bench allowed him to retire without inflicting any penalty. But it is conceived that some penalty might have been inflicted, or he might have been exposed to any action at the suit of the husband.

The record card, from the standpoint of the law of evidence, is in no better position than the evidence of the doctor himself. It is in no sense privileged. But is it admissible in evidence, and, if so, when and in what circumstances? This is a question which those responsible for the outcry about record cards in the daily papers do not pause to answer.

One thing is plain—the record card has not been made "evidence" by statute. In this respect it bears no resemblance to such a document as a death certificate, which is admissible (for many purposes) as evidence of the date and cause of death. The evidential value of an insurance medical record card must be considered according to the ordinary rules.

It is a general rule in courts of justice that the best evidence must be produced in order to establish a particular fact. Thus if the question is—Was Mr. A. suffering from influenza on January 1st, 1921? the best evidence is oral testimony of the doctor who then saw and prescribed for him. The doctor may make an entry of the fact in his diary or case-book or on the record card. But those entries are not evidence. So long as the doctor lives his testimony, given verbally in the witness box, must be adduced in order to establish the results of his diagnosis.

Suppose, therefore, a doctor were subpoenaed to produce his record card relative to Mr. A. The doctor might come to court and produce the card, but the card itself would not be evidence for or against Mr. A. It could only be used by the doctor as a memorandum made at the time to refresh his memory; but it could not be used otherwise, even if it came from official custody, unless the other party to the suit asked for and cross-examined the doctor upon it. It then becomes "evidence" of the facts recorded upon it. Its effect, as evidence, would be precisely the same as an entry in the doctor's diary.

The reason for this rule is very simple. The entry on the card was not made on oath. The lawyer treats it as mere hearsay. But, owing to the fickleness of human memory, the rule has long been recognized that any witness may refresh his memory from a contemporaneous record made by himself. The insurance medical record card might therefore be used in this way by the doctor who made the notes upon it.

The record card, however, will assume a new importance

after the death of the doctor. Entries made by him in his books or elsewhere have then an added value, and, when looked at from this point of view, that which may be written on the record card may be of great importance. It is a well known rule that entries made by a deceased person in the performance of his duty are admissible as evidence of the facts recorded; but they must have been made in the course of duty. Mere entries jotted down by a doctor in his diary are not so made. This may be illustrated by a case which was heard last year.² It was alleged that the respondent to a divorce petition was suffering from a certain disease which had been communicated to the petitioner. The doctor who had attended the respondent at the material time having died, his successor in practice was subpoenaed *duces tecum* to produce notes made by the deceased practitioner in connexion with his visits and attendances on his patients. The witness, having brought the notes to court, objected to producing them unless so ordered by the court. Sir Henry Duke refused to allow them to be read as evidence. He said that to render a note written by a deceased person admissible "it is essential that not only should it have been made in the due discharge of the business about which the person is employed, but the duty must be to do the very thing to which the entry relates and then to make a report or record of it. . . . I cannot see that any duty was cast upon this consulting physician to make these entries. He was practising alone and not in partnership, and he did not make the entries in pursuance of any duty to the persons consulting him, nor in pursuance of any statutory rule, or any binding rule of the profession. I am therefore not able to receive the entries." The same rule applies to oral statements made by a doctor.

In another recent case³ it appeared that a petitioner for divorce stated in the course of her evidence that she had consulted a medical man who made a statement to her as to the nature of an illness from which she was suffering. The doctor having died before the hearing of the petition it was contended that the statement, although it was hearsay, was admissible, as having been made in the ordinary course of duty. It was, however, rejected by Mr. Justice Bargaive Deane.

The record card, however, differs in a material respect from a mere entry in a diary. It is undoubtedly made in the discharge of a public duty, and, as such, it would be received in evidence. While not necessarily conclusive—for it might be proved, *alunde*, to be erroneous—it would go a long way towards establishing the fact which it purported to record.

One other aspect of the matter ought to be mentioned. It would be competent for the Ministry of Health to claim privilege for record cards as being confidential documents the contents of which ought not, in the public interest, to be disclosed. That public departments will sometimes object to their records being produced on this ground was illustrated in a case which came before the Divorce Court in 1919.⁴ It was there suggested that the respondent, who was in the army, had contracted a certain disease, which he had communicated to the petitioner. Application was made to the War Office for the production of the medical history sheets relating to the respondent. Counsel for the Secretary of State for War objected to producing these documents, on the ground that they must be regarded as confidential documents, and that it was not in the public interest that they should be produced. The learned judge, who refused to order the production of these documents, said, when giving judgement, "The Secretary of State has declared as to the medical reports made while the respondent was on active service, that the exigencies of the public service precluded their production, and I am not in a position to quarrel with that decision. I am therefore excluded from a valuable source of information." It is interesting to notice that in the letter which was received by the petitioner's solicitors from the War Office refusing the information, it was pointed out that the doctors who attended the respondent might be subpoenaed to give such evidence as they could from personal recollection, "but the Department has at present no information as to who they were or where they are at present to be found." It should be mentioned that in this particular case a medical witness who had examined the respondent

¹ Transactions of the Medico-Legal Society, vol. 11, p. 53

⁴ See Times Law Reports, vol. 35, p. 553.

after the period in question stated that in his opinion the respondent had never suffered from the disease in question; and the petition was in fact dismissed.

This case suggests a further inquiry. Assuming the War Office had consented to produce the medical history sheets, could they have been put in evidence unless the doctors responsible for the statements in them were called as witnesses? The answer to this may be found in the first part of this article. In the absence of the doctor who made the entries on the medical history sheets they would not have been available as evidence, unless the doctor were dead.

Whether the Ministry of Health will decline to produce record cards on the ground that they are public documents remains to be seen.

THE FUTURE OF POOR LAW INFIRMARIES.

RESUMED DISCUSSION AT THE HARVEIAN SOCIETY.

The discussion at the Harveian Society on "The future of the Poor Law infirmaries," which was adjourned from December 16th, 1920,¹ was resumed on January 27th. Dr. G. DE BEE TURTLE presided over the meeting, which was held in Paddington Town Hall.

A communication was read at the outset from Dr. F. E. FREMANTLE, M.P., who was prevented by illness from attending. He wrote that there was a danger that the Ministry of Health, which was pledged to deal with the Poor Law in the near future, might, owing to pressure on Government time, decide to make use of the infirmaries to meet present needs, and so institute an additional system, with no fixed interests or limitations, which would make still more difficult the eventual establishment of medical provision on comprehensive and efficient lines. The aim should be to provide in every unit of administration a complete system for the treatment of the whole population. As much freedom as possible should be retained for doctor and patient, and for nurses, pharmacists, and others; as much as possible should be left to private enterprise, and it should be arranged for as much payment as possible to be made by the patient, directly or indirectly, but the State should be responsible for filling all gaps and co-ordinating all factors, institutions, and departments into an efficient and economical whole. Above all, it was necessary to insist that prevention, cure, and research must go hand in hand; the growing tendency, especially under State management, to separate these aspects of medical work was a serious danger.

Dr. A. G. STEWART, Medical Superintendent of Paddington Infirmary, entered upon a whole-hearted defence of Poor Law infirmaries against common misconceptions. It was often thought that the infirmaries treated only chronic cases, but in a recent year 50 per cent. of the patients admitted at Paddington made a stay of less than a month, and 75 per cent. a stay of less than two months. Nor did these institutions deal only with the aged, for 30 per cent. of the patients admitted were under 10 years of age. Again, Poor Law infirmaries did not deal exclusively with the sick of the workhouse; only 20 per cent. of the admissions in 1914 were workhouse patients; the great majority of the patients were hardworking people whose need for relief was only due to their sickness. Over 60 per cent. of patients in his infirmary paid towards their maintenance. The prejudice against Poor Law infirmaries had been exaggerated; he had been told by several general practitioners in the district that patients preferred the infirmary to the hospital. While admitting that infirmaries were not equipped or staffed to meet the new demands upon them, he resented the suggestion that they provided little more than food and shelter. For years such work as bone-plating and grafting had been carried out at the infirmary, and hundreds of acute abdominal operations had been done annually. The nurses were as well trained, at any rate as regards private nursing, as in a general hospital. In defence of the guardians, he said that many boards took a surprisingly broad point of view, and devoted a good deal more time to their duties than the boards of governors of a general hospital. One complaint in which there was substance was as to the lack of classification of cases. But infirmaries were compelled to take in all medically deserving cases, however full they might be; they were not at liberty, like the voluntary hospitals, to set aside wards for certain classes of cases and fill up their vacancies

from waiting lists. Dr. Stewart believed that both the voluntary hospital and the infirmary had a distinct future. The first would approach matters rather from the scientific, research, teaching, and specialist point of view; the second rather from the economic and general practitioner point of view; but if there was some central authority to co-ordinate the efforts of both, great improvements would be effected and money saved. As for the staffing of the infirmary, while he had always welcomed the specialist, he was bound to say that a very large part of the work could be done equally well by the general practitioner, and he did not see why there should not be part-time general practitioners on infirmary staffs, provided—but only provided—that they demanded sufficient remuneration to justify them in giving the necessary time to the work. Infirmaries could also do a useful work in training residents to become general practitioners; there was scope also for research work and for students. In the infirmary the student would see cases likely to be as useful to him as the rarer cases to which he devoted so large a share of his attention.

Dr. REGINALD DUDFIELD, Medical Officer of Health for Paddington, said that the care of the sick must be regarded as a national duty. Since the great stocktaking of national health incidental to recruiting, emphasis had been laid upon the need for tracing the beginnings of disease. But it was rare for the failing man, as distinct from the sick man, to seek medical advice. He was withheld, not only by the prospect of doctors' fees, but also by the possibility of orders to slow down his business activities. The State must step in and relieve the failing man to some extent of his burden. The speaker was unable to appreciate the distinction between State or municipal assistance and Poor Law relief; it was merely the difference between taking money from the right-hand pocket or the left. Why should not the State or municipality be looked upon as a national charity organization society? To meet certain objections, the infirmaries should be transferred from the Poor Law to the municipal authorities; he was not in favour of the setting up of *ad hoc* authorities, which were too often wasteful in personnel and administration. The existing authorities, county or municipal, were fully competent. The infirmaries in London should be transferred to the London County Council, as recommended in the Maclean Report. With regard to staffing, there could be no doubt as to the necessity of a resident medical staff. The whole of the visiting staff need not be consultants; he would like to see the local practitioners as visiting physicians and surgeons; rosters of willing practitioners might be formed. Every ratepayer should have the right of admission to the new hospitals if such admission was certified as necessary by the practitioner in charge of the case. This right would not mean free treatment in every case, but the principle of assessment now enforced by the London County Council for the treatment of the uninsured tuberculous might be applied. While no one would be compelled to enter the institution, such entrance in certified cases should be made a condition precedent to the granting of State aid for dependants.

Dr. J. B. COOK, from his sixteen years' experience of the inside working of several Poor Law infirmaries, regretted that certain unfounded and inaccurate statements should have been made (apparently in the previous discussion). The treatment of the sick poor as now enforced by the Ministry of Health was not in the parlous condition in which it had been represented. The infirmaries took in chronic cases, of course, but they also took in numbers of cases for which the voluntary hospitals had inadequate accommodation. If the infirmaries were "the rubbish-heaps of practice" he was proud to have such rubbish on his heap. Specialists were attached to many infirmaries, both in London and the provinces. The equipment in the institutions with which he was acquainted left little to be desired. The training of nurses in the modern infirmary was quite equal to that given in the average hospital. It was not the future of the infirmaries, but that of the voluntary hospitals, which was uncertain. In his view the infirmaries should become State hospitals for their respective areas. There was room both for the infirmaries and for the voluntary hospitals with their medical schools, but if the voluntary hospitals had to curtail their activities through lack of funds the State must come to the rescue there also, either by enlarging the State hospitals, or subsidizing the voluntary ones, or doing both. The infirmaries should be more adequately staffed with resident medical officers, and specialists should be available at each infirmary to act in consultation with the resident staff as required, and also to undertake certain specialist duties such as x-ray and laboratory work and electrical treatment. Finally, paying patients should be more widely encouraged.

¹ BRITISH MEDICAL JOURNAL, December 25th, 1920.

These suggestions would not entail any vast outlay, nor would they materially upset the existing institutions.

Dr. R. H. COLE said that it would be very useful to have special clinics at the infirmaries with a view to getting at the beginnings of mental disease, but such work meant enlarged staffs and more expenditure. The part which infirmaries might play in the future from this point of view was very important and should not be lost sight of.

Mr. ZACHARY COPE spoke in praise of Poor Law infirmaries. In one such institution £800 major operations were done during a recent year. There were, however, certain infirmaries in which the work was not up to standard, and which bore out the criticisms Dr. Wilson had advanced at the last meeting. He thought there was something to be said for the policy of separating the executive from the medical and surgical side. He believed also that the Poor Law infirmaries in London might help to solve the problem of post graduate teaching, for they would bring the opportunity of clinical observation almost up to the practitioners' doors.

Dr. A. BLACKHALL-MORISON brought to the discussion an interesting communication which, however, went beyond the limits of the subject before the meeting, and entered into the question of a State medical service and the insurance controversy; in consequence of the time limit he was not permitted by the President to complete his argument. He claimed that the disadvantages of the previous situation in medicine—that is, the situation previous to recent health legislation—had been grossly exaggerated for obvious purposes. At the time when the 'incipient nationalization of medicine' was imposed upon the profession, the profession was by no means oblivious to its responsibilities. It had not neglected education or investigation. To day, however benevolent the intention of the legislature towards the community in general, its attitude towards the medical profession was one of less pronounced consideration, and in some quarters to speak at all of the interests of the profession was regarded as iniquitous. The speaker strongly protested against the charge that the profession had consulted unduly its own interests, and he claimed that an orderly freedom was the best medium in which it could grow and exercise its beneficent functions. As for the Poor Law infirmaries, these required not only more but possibly better officering, but to admit this was not to say that these institutions should be alienated from the purpose for which they had existed—namely, the care of the impoverished or necessitous poor. Persons not in that category could find all the medical attention necessary in their own domicile, and it was only these who had drawn their conclusions from institutional as distinct from domiciliary experience who could think otherwise. Both the voluntary hospital and the Poor Law infirmary would find abundant occupation when limited to their proper purpose as hitherto, and the former would obtain the support which it now lacked and would lack still more if the present subversive politics even temporarily succeeded. The speaker suggested, finally, the setting up of a central medical council, which would be a reformed General Medical Council, with greatly increased powers. This body would be responsible for the investigation, prevention, and treatment of disease. Such a council would better arrange the distribution of medical activity, charitable and other, than any lay body, however advised, which had not the full consent and sympathy of a united medical profession.

Dr. H. W. BRUCE said that as a general principle a good medical staff made a good hospital; hence the question of the medical staff of the future State hospital was important. The basis of that staff would always be the general practitioner, and therefore the desire to bring in the general practitioner was to be commended. It seemed very sound, if not essential, that there should be some close connexion between the doctors who sent the cases into hospital and those who treated them. But in these State hospitals the old accusation that medical men always sent up the expense must not be made, and the cheapest way, combined with efficiency, of providing medical attention in hospital for patients was by means of whole time general practitioners. A practitioner who was engaged partly outside and partly inside the hospital found both parts of his duty calling for him in the mornings. The speaker also referred to the function of the medical superintendent, who, he thought, should not be so overweighted with duties as at present. It was desirable that one medical man possessing the necessary authority should be simply in charge of the administrative side of a hospital, and control and co-ordinate its arrangements.

Dr. NATHAN RAW, M.P., opened with a reference to the Minister of Health, whose courage, he said, in introducing his Miscellaneous Provisions Bill was to be admired. The

speaker did not doubt that the bill would be reintroduced. The point they had to discuss that evening was not the merits of the Poor Law or the voluntary hospitals, but the best way of co-ordinating the values of all the services. The number of beds provided by the voluntary hospitals was totally inadequate to the needs of the community; hence the proposal to transfer the Poor Law infirmaries into the general municipal health service. This was not a State service, and he for one hoped they would never see a State medical service in this country, but there must be a service available for the community at large, and the question was how to provide such a service to the best advantage. He remembered that in 1897 an application was made from the Sefton Poor Law Infirmary, one of the biggest in the country, of which for a long time he had charge, for the provision of an operating theatre, and the matter from the political point of view was regarded as of such importance that the Local Government Board was called together (for the first time in many years if not in its history) to discuss the principle involved—namely, whether the Poor Law authorities ought to confine their attention to relieving the destitute as in the past, or should progress with the times and provide for the poor the latest and best treatment in the way of operating theatres, laboratories, and specialities. It was then decided that the best methods of treatment should be adopted in the infirmaries, with the consequence that a great many infirmaries were now just as well equipped as the general hospital. Another factor—the disappearance of the pauper class—had by now come into operation, there was not the same need for Poor Law infirmaries as there had been twenty years ago. The working classes of this country were being properly remunerated. He had heard many members in the House of Commons voice the sentiments of their trade-unionist constituents to the effect that neither should charity be accepted from the voluntary hospitals on the one hand nor relief from the Poor Law on the other, hence the great difficulty which the Government had to face. It was not a political question, but one of expediency. In his judgement, the Poor Law infirmaries which were really no longer required for the destitute poor ought to be taken over by the health authority of the district in which they were situated and used as general hospitals so as to be available for all. This question had come to a head on account of the difficulty of securing support for the voluntary hospitals. Those hospitals were established simply as charitable organizations, and the general public no longer desired charity. On the other hand, he believed that legally no one could be received in a Poor Law institution unless sent by the relieving officer or as a case of urgency. If it was not legal to take non paupers into Poor Law infirmaries, then the position should be legalized by transferring the infirmaries to the municipal authorities by consent. A certain amount of opposition would be raised to that policy, but in his opinion it was the only one possible.

Dr. J. C. MCIR said that the more one listened to discussions on this subject the more evident it became that the time was coming when it would be the normal proceeding for any person who was ill to go into hospital. If this were so the quality of such work which could be undertaken by voluntary hospitals must grow proportionately less, so that it seemed to be inevitable, whatever the hesitation and regret, that hospitals should be supported increasingly out of public funds. No doubt the public hospitals (the present voluntary hospitals) would continue to be the centres of teaching and research and advance, whereas the new hospitals (the remodelled infirmaries) would be the places in which the result of such advances was carried out in practice to the widest extent by the ordinary practitioner, who would have special treatment available.

Dr. C. L. TRAYLEN said that he was able to follow his patients into hospital at Willesden, and he thought it would be a great encouragement to the general practitioner if he was permitted to follow his cases into what were at present known as the Poor Law infirmaries.

Dr. WITHERS GREEN suggested that the old Poor Law service and panel service might be grouped together, and that here the infirmaries would play an important part, while paying patients should be received at the voluntary hospitals. There must be no suggestion of inferiority of medical service in one set of institutions as compared with the other. The appointments must be open to competition.

Dr. HUBERT C. PHILLIPS thought that the difficulty of appointing general practitioners to hospital posts was exaggerated. His own experience during the war as Deputy Commissioner for Bedford, as well as his experience in other capacities, suggested the contrary.

The PRESIDENT, in closing the discussion, said that

there was no doubt at all that changes were imminent. He hoped that there would be as large an amount of local autonomy as possible. The details of any particular scheme should be left to the district in which the scheme was to be worked. He was certain that, if the linking-up of institutions could be localized it would be the best plan of all so far as London was concerned. Each voluntary hospital might be linked on to two infirmaries. As for the selection of general practitioners, what better way presented itself than to make a combined medical committee of hospital and infirmary the selecting body?

TUBERCULOSIS IN 1919.

THE returns for 1919, given in the report of the Registrar-General for 1919, show a marked diminution in the number of deaths from tuberculous affections; they numbered in the aggregate 46,312 (24,550 males and 21,762 females), or 11,761 fewer than in the previous year. The crude mortality amounted to 1,258 per million—considerably below that of any previous year, the lowest hitherto having been 1,352 in 1913. The corresponding standardized rates are 1,261 in 1919 and 1,339 in 1913.

Discussion of the statistics is again embarrassed by the fact that it is considered essential to exclude the male sex, because the violent and incompletely traced fluctuations in the male population due to the war make it impossible to determine a series

of reliable and comparable mortality rates for males. In the analysis of the figures, therefore, deaths of females are alone dealt with, as in previous reports since the outbreak of war. Pre-war experience seems to justify the assumption that the trend of mortality over a few years can be established by the experience of females alone, but, as Dr. Stevenson points out, this is perhaps open to question.

It is remarkable that a fall in the mortality from tuberculosis occurred in 1919, notwithstanding the effects of the influenza epidemic which continued into the early part of the year. Dr. Stevenson gives reason for concluding that the recent trend of tuberculosis mortality can only be profitably studied by disentangling it from the mortality caused among the tuberculous population by influenza. When this is done, he considers that the figures show that the tuberculosis mortality reached a maximum in 1917, and that a decline set in during the last year of the war, and developed to a remarkable extent during the first year of peace. He considers it necessary to lay stress on these points, as in the absence of tuberculosis mortality has been the recently experienced tuberculosis mortality has been regarded as disappointing. In seeking to arrive at a conception of the course of tubercle mortality during 1918-19 an attempt has to be made to estimate what this would probably have been in the absence of the violent disturbance caused by influenza. Accordingly, the mortality of each quarter of the year is considered separately; only the second quarter was unaffected by influenza, and the other three quarters were affected in varying degrees. A diagram illustrating the mortality of females from tuberculosis in each quarter from 1911 to 1919 inclusive is here reproduced. It will be seen that after remaining at a minimum in the years 1912-14, the quarterly rates gradually increased during the three following years, but began to fall again during the first two quarters of 1918, after which the great epidemic of influenza temporarily arrested the fall, raising the rates for the next three quarters to a high level. The normal seasonal rise and fall of tuberculosis mortality shows a minimum in the third quarter and a maximum in the first or second. The second quarter was unaffected by the great epidemic, and is taken as most nearly representing the probable behaviour of the yearly

mortality if the epidemic had not occurred. The curve of the mortality of the second quarter, which was at a minimum for the three years 1912-14, rose to a maximum in 1917, and then fell to a minimum in 1919, when the lowest point was reached. There was a reduction below the nine years' average from 10 to 20 per cent. in the last three quarters' mortality, but Dr. Stevenson points out that caution must be exercised in interpreting this.

"If," he says, "influenza increased the death rate of the preceding three quarters by killing off tuberculosis patients who would otherwise have died a little later, the great fall which has occurred since the epidemic came to an end may be in part attributable to this earlier removal of persons who would otherwise have died in the quarters of low mortality."

He does not, however, consider that this is a serious source of error. There is no evidence that mortality from the non-pulmonary forms of the disease was increased by the epidemic; these non-pulmonary rates were very low in 1919, and this is thought to point to a real decline in the destructiveness of tuberculosis. The statistics do not suggest an explanation of the reason why the increase of mortality which earlier experience seemed to connect with the war should have given place to a decrease in the earlier part of 1918, while war conditions were still at their maximum. The decline in 1918 would have been even greater but for the increase of the mortality returns

from lunatic asylums; the number of the deaths in asylums fell from 5,605 in 1918 to 3,326 in 1919. The institutional mortality, however, remains very high, for the asylum deaths in 1912-14 numbered only about 1,800 a year; it is hoped that the restoration of normal conditions in asylums will lead to a further reduction of the general mortality.

Mortality of females from tuberculosis in each quarter (1, 2, 3, 4) of the years 1911-19.

The continued fall in tuberculosis mortality in both sexes at ages 0 to 5, which Dr. Stevenson considers is perhaps the most prominent feature in the recent movement of the tuberculosis mortality, was greatly accelerated in 1918. The rate used to be the highest at any age; it is now exceeded at several other ages. The age of highest female mortality was (1851 to 1890) 25 to 35; in 1891 to 1910 it was the age period 35 to 45; since 1916 the age group with the highest rate has been 20 to 25, except in 1917, when that for 15 to 20 was higher. It has been thought possible that the heavy increase of the mortality among women at ages 15 to 25 which occurred during the war was due to increased employment, but Dr. Stevenson points out that even before the war the fall in mortality was shared only to a trifling degree by females of these ages.

SINCE the Ministry of Pensions entered into possession of Ewell Colony, which has been leased to the Ministry by the London County Council for two years from November 1st for the treatment of pensioned patients suffering from shell shock, neurasthenia, and kindred conditions, 245 patients have been admitted and 28 have been discharged. The total accommodation provided is 400 beds.

THE London County Council is asking the Minister of Health to receive a deputation for the purpose of representing the urgent need for the provision of accommodation for transmigrants whilst in the Port of London, and for preventing transmigrants suffering from infectious diseases from becoming a source of infection to the population. During the past few months there has been serious overcrowding in premises utilized for the accommodation of transmigrants, and cases of favus and trachoma have been found amongst the transmigrants in London.

British Medical Journal.

SATURDAY, FEBRUARY 5TH, 1921.

THE PREVENTION OF LAMENESS AND DEFORMITY.

THE Cameron Lecture, published in this issue, is, we venture to think, worthy of the careful attention of the authorities of all medical schools. Speaking at Edinburgh, Sir Robert Jones made special reference to conditions there; but the principle involved is the same everywhere, and its importance has already been recognized by some schools, including Liverpool, and at least two in London—St. Thomas's and King's College. Briefly stated, the lecture is a plea for giving to medical students during the course of their ordinary curriculum some general idea of the principles upon which rests the department of medicine that, for want of a better name, must be called orthopaedics.

Very great progress has been achieved during the last twenty or thirty years through the application of the primary principles of physiology and pathology to the problems presented by congenital defects and the consequences of accident or disease affecting the limbs. Coupled with this development on the philosophical side have been simplifications and improvements on the practical side; aseptic surgery rendered possible many kinds of operations which the earlier orthopaedic surgeons did not dare to attempt, and almost at the same time Thomas of Liverpool devised methods and appliances which in their directness and simplicity bore the stamp of genius. The study of his methods afforded a starting-point for a few ardent spirits in this country and America, who have advanced the department of orthopaedics to its present position. Not only are the principles which should guide the treatment of congenital deformities and of fractures better understood and the methods of treatment greatly improved, but ideas on the treatment of infantile paralysis, and to some considerable extent of tuberculosis of bones and joints also, have been profoundly affected. We now see more plainly that early treatment can do much, and have learnt what the nature of that treatment should be. It is perhaps true that there has been, on the part both of the profession and of the public, a disposition too readily to accept deformities as inevitable evils, and undoubtedly the task of those few surgeons who have given special attention to their remedy has been made harder because treatment has not been attempted at a sufficiently early date. The war produced an enormous number of injuries of the limbs, and observation made plain the ill effects of delayed or imperfect treatment, and demonstrated the remarkable success to be obtained when well-devised methods were early instituted. It is, for instance, astonishing to be told that in the three hundred cases of fracture of the femur in the special military hospital at Edmonton at one time the average shortening was less than half an inch, and that at the Alder Hey military hospital results equally good were obtained from the use of Thomas's splint in its original simplicity.

We have a fairly well defined set of conditions which, though due to different causes, have two

things in common: first, that their treatment calls for the application of the same or similar principles and appliances, and secondly, that they are of great economic importance. Further, it is agreed that treatment on the correct lines ought in all cases of this class to be instituted at the very earliest date. Even if the practitioner is not himself prepared to undertake the initial manipulations, where such are necessary, it is important that his training as a medical student should have included sufficient instruction in the principles and methods of orthopaedics to enable him to judge what can be done, and when it can best be done, and to conduct the after-treatment, for which, indeed, the operations and manipulations of the specialist are only preparatory.

We entertain no doubt that the case for a special orthopaedic teaching department in every medical school has been fully made out, and we believe that anyone who looks into the facts must arrive at the same conclusion. The plan proposed seems to be in line with recent developments in the organization of medical education, which have been designed to render it possible for the student, within the time available, to receive a grounding in all the many subjects his acquaintance with which must be sufficient at least to enable him in after-life to judge their relative importance. We do not mean that cases of this nature should be withdrawn from the scope of the general surgeon; the contention is that there should be a special teaching department in which every student should receive instruction in principles he ought thoroughly to understand. Nor will it lay another burden upon the student; he is not asked to give more time, but is offered greater facilities for acquiring knowledge in a department of practice with which it is essential he should be acquainted when he goes into general practice. If he will then have relatively few cases of fracture to treat, he will certainly be consulted about many congenital deformities, and will have to treat the results of acute anterior poliomyelitis, tuberculosis of bones and joints, and often rickets. It may be that in some medical schools it will at first be difficult to make the readjustments necessary for the establishment of an orthopaedic department under a special surgeon, but that these difficulties can be overcome is proved by the plan described by Sir Robert Jones as already in force at the Liverpool Royal Infirmary and St. Thomas's Hospital; King's College Hospital also has established an orthopaedic teaching department. We cannot suppose that Edinburgh, the largest medical school in the British Empire, with traditions envied by all, to quote Sir Robert Jones's estimate, will lag behind. The moment is favourable for action, when the lessons of the war are still fresh in the minds of the profession and of the public.

THE INDUSTRIAL FATIGUE RESEARCH BOARD.

IN the *Scotsman* of January 24th the categorical announcement is made that "the Treasury have intimated that after the end of March they will not be able to continue any allowance to the work of the Industrial Fatigue Research Board, which it is suggested should be dissolved, and the work undertaken by other authorities or borne by the industries themselves." Our contemporary optimistically holds that this decision "will incur the opposition of practically all progressive employers and labour leaders," and directs attention to the importance of the work already carried out by the Board's staff, instancing

the researches of Dr. H. M. Vernon into the methods of the iron and steel industry, of which we gave some account a fortnight ago (January 22nd, p. 131). The history of this Board is so instructive that we may be permitted to recall certain facts. Three years ago, in December, 1917, the Department of Scientific and Industrial Research was invited by the Home Secretary to appoint a committee to investigate the subject of industrial fatigue on comprehensive and systematic lines. The suggestion was welcomed by those to whom it was addressed. It was apparently felt that a more imposing body than a mere temporary committee was needed, so the Department of Scientific and Industrial Research and the Medical Research Committee (as it then was) appointed a Research Board to organize and direct researches falling within the following terms of reference: "To consider and investigate the relations of the hours of labour and of other conditions of employment, including methods of work, to the production of fatigue, having regard both to industrial efficiency and to the preservation of health among the workers." The personnel of the Board now includes the President of the Royal Society, who has been chairman since the Board's inception, two other distinguished Fellows of the Royal Society, Sir Joseph Petavel, Director of the National Physical Laboratory, and Dr. C. S. Myers; also two leading authorities on industrial medicine, Dr. T. M. Legge and Professor E. L. Collis, and such representative employers of labour as Mr. W. L. Hichens, Chairman of Cammell, Laird and Co., and Dr. Kenneth Lee, of Messrs. Tootal, Broadhurst, Lee and Co.

The task entrusted to the Board under the terms of reference was immense. Before the pioneer researches of the Health of Munition Workers Committee (under the leadership of the present Chief Medical Officer of the Ministry of Health) practically no systematic scientific investigations of the human factor of industry had been carried out. The Health of Munition Workers Committee reached various important conclusions which, like most good scientific work, pointed the way to other urgently needed researches. But the supply of trained investigators was small; it consisted, indeed, only of those who had been employed by the Health of Munition Workers Committee. The Board had therefore, in the first place, to assemble and train a staff, and to deal with such problems as its immediate resources enabled it to investigate. The first annual report, issued only a few months ago, recorded a very promising start, and thirteen reports have already been published or are at press. These include the report by Dr. H. M. Vernon above mentioned, which contains, *inter alia*, an extensive analysis of the sickness and mortality experienced by 24,000 iron and steel workers which is of great interest to the student of industrial morbidity. Another investigator of the Board, Mr. P. M. Elton, has made a report upon the production in silk weaving which brings out the detrimental effect upon output of working by artificial light; while Dr. Vernon, in another memorandum, has shown that although increase in hourly output follows at once upon reduction of hours the converse is not true, but a fresh state of equilibrium takes time to establish.

To the trained man of science, familiar with the difficulties of investigating a new field, the slow evolution of an appropriate technique, and, above all, the pains needed to organize a staff, the achievements of the Board in its first year will seem creditable. Such a person might suppose that the eminent men of science who have devoted time and thought to what,

in 1917, was regarded as a matter of vital national importance, would be given an opportunity to build upon the foundations they had constructed. But to judge from the paragraph in the *Scotsman*, any such supposition would be wide of the mark. The President of the Royal Society and his colleagues may be gratified as taxpayers at this new success of the economy campaign, even if, as men of science, they may feel some little disappointment at the outcome of their labours. After all, 1917 was a long time ago, and the financial condition of the country was no doubt eminently prosperous then; it could hardly have been foreseen that in 1921 there would be any real need for economy, while the officials of the Treasury no doubt expected that the Board's terms of reference would have been discharged within two years at most; this is the view that any administrator devoid of scientific training would naturally take.

We have at least the satisfactory assurance that knowledge will continue to be acquired, since, as we understand, similar research organizations have been created by the Governments of the United States and France. These organizations will have derived advantage from the spade-work of the English Board, and their results will, with due regard for economy, be abstracted in the English journals.

A cynic has remarked that the wise father will always steadily prophesy evil of his son, since, whatever happens, either his paternal feelings or his intellectual vanity will be flattered. We have often expressed the fear in these columns that the war-time enthusiasm for science in general and for medical science in particular, having no root in an educated public opinion, would wither away, so that we cannot pretend to be surprised by the fate which has overtaken the Fatigue Research Board: it is precisely what we should have anticipated. But there is one point which specially concerns the medical profession. According to its last report, the Medical Research Council is in some sense responsible for the Fatigue Research Board, and, presumably, approved its plans. Are we to infer that the action of the Treasury, as expounded by the *Scotsman*, is to be interpreted as a hint to the Medical Research Council, like that of Flamininus to the Achaean League? If so, what are the limits of the shell beneath which the head of the tortoise is safe? The time may not be far distant when other objects of research yet more intimately connected with the progress of general and preventive medicine will be consigned by the Treasury to the scrap-heap.

We have not told this story for the mere journalistic pleasure of criticizing a Treasury decision. If the facts are as stated by our contemporary, and if the decision to dissolve the Board and dismiss its staff has been reached suddenly and only communicated to those concerned within a few weeks of its contemplated coming into effect, it is undeniable that so honoured a member of our profession as the President of the Royal Society has been treated with discourtesy and avoidable hardship has been inflicted upon younger investigators. But, in these times, discourtesies and even hardships are no great matters. What is of vital importance for us all to realize is that the ideals of science, instead of counting for more, count for much less than six years ago. Viewed from this aspect, no more instructive incident could have happened. Abstractly considered, scientific research could hardly be presented to the British public in a more inviting shape than that provided by the terms of reference and the personnel of this Fatigue Research Board. The terms of reference made an appeal both to the spirit of humanity and to the

yearning for industrial efficiency—it were, perhaps, too harsh to say to the cupidity—of the average Briton. A combination of the holder of the greatest honour in British science with the foremost representatives of organized industry would seem unshakable. That a scheme launched under such hopeful auspices should be shipwrecked almost at the beginning of the voyage is indeed a portent.

"We are witnessing," said Dr. Inge in last year's Galtón Lecture, "the decline and fall of the social order which began with the industrial revolution 160 years ago. The cancer of industrialism has begun to mortify, and the end is in sight." That a national application of scientific method to the study of the human side of industrial organization is one of the first things to be sacrificed when expenditure must be curtailed, is a proof that the Dean of St. Paul's has accurately diagnosed the case.

THE LONDON UNIVERSITY LABORATORY

A few weeks ago a brief account was given of the circumstances which threaten the early closure of the Physiological Laboratory of the University of London, and regret was expressed that the Senate should have rather tamely acquiesced in the extinction of the one laboratory under its direct control. Briefly the story is this. The Laboratory was established in 1902; the University granted the use of the top floor (then unused) of that part of the building of the Imperial Institute, South Kensington, which it occupies, a sum of £4,000 was provided by private benefactors for equipment. Professor A. D. Waller has been director, unpaid, from the first. The cost of upkeep is about £1,300 a year, of this the London County Council has provided £500 and the University the remainder. There is no question of the efficiency of the Laboratory and of the value of the work done there. It has had a great influence on the progress of physiology, for it is a research laboratory with an organization for higher teaching—for teaching the teacher, in fact. In 1906 Convocation took it as a model upon which other university research laboratories and courses of advanced lectures might be formed. In 1908 the Senate received and endorsed identical reports from the Academic Council and the Council for External Students, to the effect that it was highly desirable to continue the work of the Physiological Laboratory as forming a valuable part of the work of the University. The present unfortunate state of things has been brought about, or at least precipitated, by the London County Council's announcement that it intends to stop its grant of £500 a year. Thereupon the Senate, on December 15th, resolved that, failing the assurance of adequate support from the County Council or other sources before the end of March, the Laboratory must be closed not later than the end of next July. It seems a poor little economy for either of these public bodies to attempt—poor in spirit and little in amount. The Senate is said to be influenced also by a desire to obtain more space for its clerical staff, but at present the key of the situation is in the hands of the County Council, and we trust that it will listen to the advice tendered to it. At its first meeting after the Senate's decision was known the Physiological Society unanimously adopted a resolution expressing its opinion that the closure of the Laboratory "would be a grave injury to the advancement of science and knowledge and to the teaching of physiology in London, and would therefore be contrary to the public interest." This view is generally held in the medical profession and by all men of science. It is that of the teaching profession, and, indeed, it must be shared by the great majority of educated persons in London and throughout the country.

CONGRESS OF RADIOLOGY AND PHYSIOTHERAPY.

THE first Congress of Radiology and Physiotherapy, organized by the Electro-Therapeutic Section of the Royal Society of Medicine and the British Association of Radiology and Physiotherapy, will be held in London on April 14th, 15th, and 16th, 1921, under the presidency of Sir Humphry Rolleston, K.C.B. The opening ceremony will take place at the Royal Society of Medicine on Thursday, April 14th, at 10 a.m. The work of the Congress will be divided into three sections—Radiology, Electrology, and Physiotherapy—and at each session opening papers will be read by representatives of France, Belgium, and England. All communications may be made in French or English. In addition to the set discussions and demonstrations, visits will be paid to the radiographic and electrical departments of selected hospitals in London. The Sections of Electrology and Physiotherapy at a joint meeting will discuss the re-education of muscles, which has formed the subject of recent correspondence in our columns. In connection with the Congress there will be an exhibition of electrical and X-ray apparatus, and the social functions will include a Congress dinner and a visit to the universities of Oxford and Cambridge. On Saturday afternoon, April 16th, there will be a demonstration of physical training, organized by the Ling Association, at the Albert Hall. The subscription for English members is 2 guineas; that for French and Belgian members 40 francs. The Secretary General is Dr. G. Harrison Orton, and the honorary treasurer Dr. J. Metcalfe, to whom subscriptions should be addressed at the Royal Society of Medicine, 1, Wimpole Street, W.1.

THE PANDEMIC OF INFLUENZA

THE report on the pandemic of influenza (1918-19), which has been issued by the Ministry of Health, is, both from the scientific and from the practical or clinical point of view, a contribution of no little value to medical literature.¹ It consists of three parts: the first, dealing with the epidemic in Great Britain and Ireland, has been prepared by Dr. Major Greenwood and Dr. Thomas Carnwath, in collaboration with Dr. Herbert French and Sir Frederick Andrewes. A history of influenza in England from 1658 to 1911 is followed by a discussion of the statistics of 1918-19 in the United Kingdom, and this by an article from the pen of Dr. Herbert French on the clinical features of the epidemics of 1918-19, illustrated by coloured drawings and numerous charts. Appended is a long bibliography covering the years 1914-1920. Sir George Newman in his introductory note states that all observers are agreed as to the difference of the characters of the two waves, the first in June and July, 1918, the second in October and November. The first was of the three-day fever variety, not of virulent type, but remarkable in that it attacked youth especially. Damage to the capillary vascular system caused haemorrhages in the mucous and serous membranes, the respiratory tract, and the lungs, epistaxis was common. The condition is said in some ways to have resembled a bacteraemia, localized in particular in the pulmonary blood vessels, haemorrhage paving the way for secondary infections. The second wave was of a much more severe type. It was often attended by early acute infective pulmonary inflammation, while in other cases the symptoms early assumed the type of a virulent toxæmia or septicaemia. Sir Frederick Andrewes contributes a chapter on bacteriology, in which the part played by Pfeiffer's bacillus is fully discussed. Speaking of the evidence obtained from the epidemic of 1918, he says that the position of Pfeiffer's bacillus as the primary cause of the disease has been in no way strengthened. "Its case remains unproven and the crucial tests to which it has been submitted

¹ Ministry of Health Report on the Pandemic of Influenza. Reports on Public Health and Medical Subjects No. 4, 1920. H.M. Stationery Office (L.C. 101).

seem to indicate it rather as a secondary infection than as the primary 'materies morbi.' At the same time it cannot be asserted that, as a primary cause, it is wholly out of court. The evidence for a filter-passing virus as the primary cause of the disease is suggestive, but at present a final verdict cannot be given. The complications to which the epidemic has owed its abnormal fatality have been due to secondary infections in which Pfeiffer's bacillus and the haemolytic streptococcus have played a predominant part." Other chapters follow, including one on the general and special prophylaxis of influenza; here the hope is expressed that eventually vaccine prophylaxis may be placed upon a securer foundation than it yet possesses. Meanwhile, it is said that "the non-mystical methods which come within the scope of personal hygiene are those which both epidemiological and physiological research sanction." The second part of the volume presents an account of the incidence of influenza in Europe and the Western Hemisphere by Dr. R. Bruce Low, C.B., and of its incidence in Australasia and parts of Africa and Asia by Dr. S. P. James. The third part consists of a series of twelve papers reporting inquiries into different aspects of influenza as it occurred in this country. It contains results of a special study of the epidemic in Manchester by Dr. Niven and his colleagues, and by Dr. T. Carnwath, and a paper also by Dr. John Brownlee on the periodicity of influenza. We hope to refer in more detail to some of the articles in this interesting volume, which contains 600 pages, in future issues.

THE MACDONALD PRESENTATION FUND.

We have received from Dr. Noy Scott, Honorary Secretary of the Plymouth Division of the British Medical Association, a letter expressing surprise that a larger number of members of the Association have not hitherto joined in the tribute of gratitude and regard to Dr. J. A. Macdonald afforded by the testimonial fund now opened. The only cause must be, he thinks, procrastination, for no member of the British Medical Association, nor any insurance practitioner, can be unaware of the great and self-sacrificing services Dr. Macdonald has for so many years rendered to the Association and the profession at large. The appeal for subscriptions to the presentation fund was published in full in the *JOURNAL* of July 24th, 1920. It was addressed to all members of the British Medical Association, and was signed by the President, the Chairman of Representative Meetings, the Treasurer, and by past Chairmen of Representative Meetings. After reciting briefly Dr. Macdonald's distinguished record of work for the profession, it proceeded: "In short, for the last seventeen years, whenever the Association has required exceptional services demanding sound judgement, devotion to the interests of the profession, and a commanding personality, it has called on Dr. Macdonald, and never in vain." The Council believes that members will desire to show their gratitude to Dr. Macdonald in a fitting and adequate manner. Subscriptions of any amount will be welcomed, but no individual subscription may exceed five guineas. Cheques should be made payable to "The Macdonald Presentation" and sent to the Medical Secretary, 429, Strand, London, W.C. 2.

A CANCER SERUM.

MENTION was made in the daily newspapers some months ago of a claim made by or on behalf of Dr. Glover of Toronto, to have prepared a "serum" which was alleged to have the power of curing or checking cancer. Last October the Toronto Academy of Medicine appointed a committee to inquire into the matter, and its interim report was presented on January 13th. The committee conducted its inquiry under two heads—experimental and clinical. As to the first, it was claimed that Dr. Glover had cultivated cancerous cells, and from them had cultivated and isolated an intracellular organism which he had found present only in cancer, and in every type of cancer.

It was further claimed that by inoculation of these cells and organisms cancer had been produced in a number of animals—pigeons, rats, mice, rabbits, guinea-pigs, and hens—and that by injection of cultures of these cells and organisms into the jugular vein of a horse a serum had been obtained which, when injected into the experimental animals, rendered them immune to inoculation by the cancer cells and organisms above mentioned. In other words, animals previously treated by the serum were immune, while those not so treated developed experimental cancer. The committee reports that Dr. Glover refused to permit representatives of the committee to visit his laboratories or to allow the committee to examine his cultures and experimental material at present available; he did not accede to a request to demonstrate his ability to cultivate cancer cells and organisms, nor did he demonstrate his ability to produce cancer by inoculation or to immunize animals against it. The committee therefore reports that it has no evidence to substantiate Dr. Glover's claims on the experimental aspect of the question. On the clinical side the claim was that the serum injected in cases of human cancer had been found capable of producing improvement or cure. The committee examined twelve of fifteen cases selected by Dr. Glover. It sought to obtain from the medical attendants of the patients confirmation of the diagnosis, and a statement as to the clinical condition of the patient before applying to Dr. Glover. It also obtained a list of cases treated in St. Michael's Hospital, only those cases being included which had received at least five injections. The committee also sought to obtain from Dr. Glover a complete list of the cases treated by him privately, and from Fellows of the Academy, from other practitioners, and from the hospitals, reports of the results of serum treatment in cases which had come under their observation. The committee's examination of the data from all these sources afforded it no evidence to warrant a hope that a specific cure for cancer has been discovered by Dr. Glover, or that a cure has been produced by the serum in any case definitely established as cancer. With regard to the further question, whether the serum produces improvement in cases definitely established to be cancer, the committee reports that it has not obtained evidence of any apparent improvement greater than that which may occur spontaneously in certain cases of cancer. It notes that good results are at times observed in cases supposed to be cancer, but in which the nature of the condition has not been established on incontrovertible evidence; in such cases, it is added, the usual conclusion of the medical attendant is that his diagnosis was wrong. In concluding its interim report, the committee states its readiness to examine any data Dr. Glover may decide to place before it, and to collaborate with recognized authorities who have already expressed their willingness to do so, or with others whom Dr. Glover himself may nominate. We gather that the committee will not go further into the matter unless Dr. Glover supplies to it details of his methods sufficiently definite to permit of a repetition of the experiments by independent workers.

SPIROCHAETOSIS ICTERO-HAEMORRHAGICA.

WORK in connexion with spirochaetosis ictero-haemorrhagica, formerly known as Weil's disease, and now often spoken of as infective jaundice, though it is one example only of a rather large group, has been mainly directed to its etiology, pathology, and epidemiology; and it must be admitted that the study of its clinical manifestations has been less conclusive, though Inada's (1917) correlation of the clinical course with the pathological changes must not be forgotten. In his recent clinical analysis of 55 cases Dr. J. A. Ryle,¹ who was in close touch with the disease during its prevalence on the Western front, has taken steps to redress the balance. Although some cases occurred in the base hospitals during the winter of 1915-16

¹ J. A. Ryle, *Quart. Journ. Med.*, Oxford, 1921, xiv, 153-170.

it was in the summer and autumn of 1916 that an epidemic, of probably not more than 200 cases all told, involved the British army in a confined section of the forward trench zone near Ypres. The infected areas were wet and ill drained, and the case incidence increased after a wet spell and decreased after dry weather. The absence of any further epidemics on the Western front may, like the considerable diminution in the number of rats, which are the accepted carriers of the infection, have been due to the great increase in the use of poisonous gas. Out of the 55 cases, 40, or 73 per cent., had jaundice, the remaining 15, or 27 per cent., being free from icterus; and the mortality of 3, or 5.4 per cent., was confined to the cases with jaundice, although non-icteric patients were often as severely ill as the icteric cases. The onset is characteristically sudden, and the initial febrile period lasts on an average ten days, being followed by a subnormal temperature for one to six days; 18 per cent. of the cases relapsed or showed recurrences, but the relapses were not necessarily accompanied by jaundice or grave signs; this last observation recalls Inada's very definite view that the return of fever is not due to spirochaetal activity, but to the reabsorption of spirochaetal toxins, and therefore is not a true relapse, and that the symptoms are merely those due to an elevated temperature and are not a repetition of those characterizing the original attack. Vomiting is a constant symptom of the disease and when frequent and persistent is a bad prognostic. The clinical features in the 55 cases show some differences from those of the disease in Japan, and also as described in pre-war literature; thus the mortality was much lower in France; the spleen, which was palpably enlarged in 10 per cent. of the Japanese cases and was a prominent feature in the descriptions given before the spirochaetal nature of the infection was discovered, was never found to be enlarged; increase in size of the liver was reported in 2 cases only; and herpes labialis, practically always haemorrhagic, occurred in 44 per cent. of the 55 cases. In other respects the recognized manifestations corresponded fairly well; albuminuria was noted in 58 per cent., acetoneuria in 16 per cent., and pains in the legs in 44 per cent. In spite of the septicæmic nature of the disease, there was little evidence of any direct or permanent damage to the heart, and clinical evidence of cardiac dilatation was forthcoming in one case only. The average high limit of the pulse rate was 100, and a slow pulse, usually lasting for a short period, was common soon after the temperature had fallen. Epistaxis was noted in 9 cases, haemoptysis in 16; the extravasation of blood was referred to lysis of the capillary walls as a result of the septicæmic state, and not of the jaundice. The absence of haemoglobinuria and of increased fragility of the red blood corpuscles rendered haematogenous jaundice improbable, and the cause was thought to be obstruction in the radicles of the bile ducts; the possibility of excessive secretion of bile due to irritation of the liver cells is mentioned, but Drule's contention that the jaundice is due to disordered function of the liver cells and is quite independent of obstruction is not considered. The differential diagnosis, especially of the early stages and of the cases without jaundice, in which trench fever proved the main stumbling-block, is fully discussed.

ANTHRAX FROM SHAVING-BRUSHES.

A CIRCULAR issued by the Ministry of Health draws attention to the recent occurrence of cases of anthrax in man, including some fatal cases, in which infection has been traced to the use of contaminated shaving-brushes. In the *JOURNAL* of January 3rd, 1920, p. 25, we recorded a protest by Dr. H. T. Maw against the importation of foreign-made (especially Japanese) shaving-brushes because of the insanitary conditions under which they were manufactured, and the possibility of infection

by anthrax; special reference was made also by Dr. Maw to other brushes used for medical and toilet purposes, such as throat-brushes and tooth-brushes. In consequence of the number of random samples found infected, an Order in Council was issued in February, 1920, prohibiting the further importation of Japanese shaving-brushes into this country. Steps were taken to secure the destruction of brushes from consignments known to be infected, and all importers of and wholesale dealers in Japanese shaving-brushes were warned of the possible danger to persons becoming possessed of these brushes. Owing to the difficulty of tracing brushes imported before the prohibition took effect there is reason to believe that there must still remain in the hands of retailers a considerable number of shaving-brushes of Japanese origin which may be infected. Medical officers of health are asked, therefore, to communicate with all retail chemists and other dealers in shaving-brushes in their districts and warn them of the serious results which may follow from the distribution of Japanese shaving-brushes which they may still have in stock. Such brushes should either be destroyed or securely wrapped up and returned to the wholesale dealers from whom they were obtained, with an accompanying explanation. An improved method for the partial disinfection of shaving-brushes before use is recommended by the Ministry of Health; complete sterilization is impracticable, as disinfection will not affect spores embedded in the handle of the brush. The brush should first be thoroughly washed with soap and warm water containing a little washing soda, and allowed to stand for half an hour in a warm solution of formaldehyde (1 part of 40 per cent. formalin and 16 parts of water—a 2½ per cent. solution of formaldehyde); then it should be allowed to dry. In regard to the treatment of a case of anthrax, it is now recognized that the best method is physiological rest of the part affected, combined with intravenous injection of anti-anthrax serum—60 to 80 c.cm. on the first day, and 60 c.cm. on the day following. Subcutaneous injection into the abdominal wall of 30 c.cm.—repeated if necessary on successive days—has apparently been successful in many cases. Excision is now no longer recommended as an adjunct to the serum. The use of normal ox serum, referred to in a leading article in our issue of December 4th, 1920, has not yet had sufficient trial to displace treatment by anti-anthrax serum.

"JOURNAL OF LARYNGOLOGY AND OTOTOLOGY."

FROM the beginning of the present year the monthly *Journal of Laryngology, Rhinology, and Otology* has, with the alteration in its title given above, entered upon a new phase in its existence. Founded as the *Journal of Laryngology and Rhinology* thirty four years ago, by Morell Mackenzie and Norris Wolfenden, it has now been purchased from the publishing firm who owned it by members of the profession, for whom it will in future be published by Messrs. Oliver and Boyd, Edinburgh. No radical changes are to be expected in the scope and policy of the journal, but it is hoped that under the new conditions it will appeal to all medical men interested in otolaryngology, not only in the British Isles, but in the Overseas Dominions and in America. Laryngology as a special branch of surgery was cradled in Britain, and most of the great advances made in it have been of British origin. With the increasing number of workers in the speciality further advances in knowledge are to be anticipated, whether sought in the laboratory or by clinical observation in the out-patient departments and wards of hospitals. We look confidently, therefore, for a still larger and more valuable output of original contributions in the pages of the *Journal of Laryngology and Otology*. The January number reflects great credit on the new management, and on the editors, Dr. A. Logan Turner and Mr. J. S. Fraser.

CHINESE HONOURS FOR MEDICAL MISSIONARIES.

THE Chinese Government has conferred the Order of the Chia Ho, 5th Class, upon three British medical missionaries—Drs. Davenport, Cousland, and Gillison. Dr. Cecil J. Davenport was President of the China Medical Missionary Society during three years of the war, and recently presided at the Medical Conference held in Peking. He receives the Chia Ho for pioneer work in Chungking and Wuchang, and also for his work since 1904 as chief of the Shantung Road Hospital. He has seen thirty-one years' service in China. Dr. Philip B. Cousland was formerly at Chaochowfu, Fukien Province; he is now engaged in translating foreign medical books into Chinese and in helping to form a Chinese medical terminology. The decoration is bestowed for long and useful service in pioneer medical and literary work during thirty-seven years in China. Dr. Thomas Gillison worked for nearly thirty-five years in Hankow, and is now engaged in teaching and literary work in the Shantung Christian University, Tsinan. The award is in recognition of pioneer medical work in Central China, and of educational and literary work in Hankow and Tsinan.

A MEETING of Lord Cave's Committee on Voluntary Hospital Finance was held on February 2nd at the Ministry of Health, when evidence was given in the morning by Sir Cooper Perry and Mr. Maynard on behalf of the King Edward VII Hospital Fund, and in the afternoon by Mr. Verity, Chairman of Charing Cross Hospital. On February 3rd Mr. Vernon Miles gave evidence on behalf of the small general hospitals in the London area of the British Hospitals Association.

Dr. Percy Kidd, consulting physician to the hospital, has been elected Schorstein Memorial lecturer for 1922 at the London Hospital Medical College. The lecturer for this year is Dr. A. G. Gibson of the University of Oxford, who will give his lecture on chronic inflammatory diseases of the spleen on June 3rd.

DURING the twenty years that the Nobel Prize has been awarded there have been 101 prize winners, consisting of 23 Germans, 20 Frenchmen, 9 Englishmen, 8 Swiss, 6 Americans, 6 Swedes, 5 Dutch, 5 Danes, 4 Belgians, 4 Italians, 3 Austrians, 2 Norwegians, 2 Russians, 2 Spaniards, 1 Scotsman, and 1 Indian; 97 were men, 28 have died.

ROYAL MEDICAL BENEVOLENT FUND.

At the meeting of the Committee held on January 11th, 1921, twenty-four cases were considered, and £255 voted to eighteen applicants. The following is a summary of some of the cases relieved:

Daughter, aged 68, of M.R.C.S. Eng. who died in 1874. Applicant has supported herself for some years by the teaching of drawing and painting, but owing to age and deafness is now unable to obtain pupils. Only certain income £26 a year and a gift from friends of £10. Rent £20 per annum. Voted £18 in twelve instalments.

Daughter, aged 44, of F.R.C.S.I. who died in 1899. Applicant shares a cottage with a friend, and they make a small income by taking boarders. Total income 1920, £75. Relieved once, £10, January, 1920. Voted £10.

Widow, aged 53, of M.R.C.S. Lond. who died in 1911. Applicant earns her own living by giving music and singing lessons. Her daughter, aged 26, helps her aunt, with whom she lives, but owing to a breakdown the doctor orders her away for a rest, and applicant asks for help to defray the expense. Relieved six times. Last time £10 in two instalments, December, 1918. Voted £15 in two instalments.

Daughter, aged 48, of F.R.C.S.I. who died in 1899. Applicant shares house with a friend, and they derive and share a small income from letting rooms. Applicant's total income during last twelve months, £40. Relieved once, £10, January, 1920. Voted £10.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters J. Symonds, K.B.E., C.B., F.R.C.S., at 11, Chandos Street, Cavendish Square, London, W.1.

The Royal Medical Benevolent Fund Guild is overwhelmed, in these days of exorbitant prices for clothing and household necessities, with applications for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for the benefit of the hand clothes and household articles for the benefit of the widows and children who in happier times would not have needed assistance. The gifts should be sent to the Secretary of the Guild, 43, Bolsover Street, W.1.

Scotland.

THE CONSULTATIVE COUNCIL'S MEDICAL SERVICE SCHEME.

THE Scottish Committee of the British Medical Association has referred the report of the Scottish Medical Consultative Council to the Divisions in Scotland. As will have been seen from an analysis of the report published in our columns of December 11th it embodies a medical service scheme. Before formulating any statement on the scheme the Scottish Committee will await the replies of the Divisions, and though there will be a meeting of the Committee on February 10th it is not likely that many replies will have been received by that date. The Committee, however, may think it necessary to take some notice of the letter criticizing the scheme which the Medical Guild has circulated to the profession in Scotland. The letter, which is signed by the president of the Guild, Emeritus Professor F. M. Caird, and the honorary secretary, Dr. Frederick Porter, directs particular attention to the fourth recommendation of the Consultative Committee, which advised that "the present medical service for the insured should be expanded, so as to provide everything that is still necessary to make it adequate and complete, and extended so as to include within its scope the dependants of the insured, all persons (including dependants) of the same economic status as the present insured class, and all now entitled to medical service under the existing Poor Law." The Guild expresses the view that this means "that every tradesman, shopkeeper, and all others with incomes under £250 per annum, along with their wives, children, and others who may be dependent on them, will be provided with a State doctor." In many districts, including small towns and villages, this will, it is considered, leave very few private patients. As the State family doctor will have over him a junior and senior district medical officer to supervise his work, his position, it is argued, will "be lowered to the status of a scullery-maid in a State medical kitchen." The Guild has drawn up a memorandum, which it asks its correspondents to approve. The memorandum contains these passages:

"The family doctor is to be a State doctor, remunerated, presumably at a contract rate. The patients are to be State patients; they are no longer to be the doctor's private patients. The doctor becomes a departmental official, and the patient a name in the departmental directory.

"It is further proposed to have two grades of officials below the doctor. The one is the State nurse, who will enter the sick-room as a State servant, not with the beneficent influence of the present district nurse to help as she finds it practicable. The other is the health visitor, who is to act as a sort of State mother to the family, and is to officially instruct the mother how to treat her children. In the event of sickness, if the official opinion be that the house is too small, the sick person is to be removed to a 'hospice' or to 'recovery rooms,' which it is proposed to provide all over the country.

"There is no attempt to estimate the cost of this scheme, but it must be very great. When the country is groaning under the enormous burdens of the war, the proposals can only be regarded as monstrous."

The memorandum expresses the view that the State should cease to interfere with medical attendance on sick people other than those who belong to the necessitous classes, so long as the sick are not a danger to the community by reason of infectivity. A letter by Dr. Buist on this subject is printed in the SUPPLEMENT.

SCOTTISH REGIONAL HOSPITALS COMMITTEE.

A Regional Committee in Scotland of the British Hospitals Association was formed at a meeting of hospital managers and administrators held in Glasgow on January 25th. Colonel D. J. Mackintosh, C.B., M.V.O., Medical Superintendent, Glasgow Western Infirmary, occupied the chair. The Regional Committee, it was pointed out, would be an integral part of the British Hospitals Association, and only those who joined the parent body would be eligible for membership. The Committee will consider matters affecting voluntary hospitals, and take such steps to safeguard their interests as may be considered necessary. Colonel J. A. Roxburgh was appointed chairman and Dr. D. Campbell Suttie honorary secretary. An executive committee composed of representatives of groups of hospitals was appointed.

CENTRAL MIDWIVES BOARD.

At a meeting of the Board held in Edinburgh Sir Halliday Croom, in a valedictory address on his retirement from the Board, thanked the members for the loyal support he had received as chairman, and referred to the pleasant and harmonious way in which the work had been carried out. On the motion of Dr. A. Campbell Munro, seconded by Sir Archibald Buchan-Hepburn, a hearty vote of thanks was accorded to Sir Halliday Croom for the efficient manner in which, during a period of five years, he had discharged the important duties of chairman of the Board since its formation. The Board also expressed its appreciation of the able and valuable services rendered by Mr. D. L. Eadie, the secretary. The constitution of the new Board is announced in the SUPPLEMENT this week at p. 31.

Ireland.

VISIT OF SIR GEORGE MAKINS TO BELFAST.

SIR GEORGE MAKINS was entertained to dinner by the Council of the Ulster Medical Society and a few friends on the evening of January 28th; he also was shown over the hospitals, and on Saturday, 29th, was taken down to the well-known golf links at Newcastle to try his skill with some of the local medical talent. It gave all those who had met Sir George in France the greatest pleasure to welcome him to the North of Ireland, and his reputation had been spread by those who returned after serving, so that the warmth and heartiness of his reception was general, and his visit was greatly appreciated.

ULSTER MEDICAL SOCIETY.

The sixth meeting of the session was held in the Medical Institute, Belfast, on January 27th. The President, Dr. Thomas Houston, occupied the chair, and there was a large attendance. The President presented the Certificate of Honorary Fellowship to Major-General Sir George Makins, G.C.M.G., ex-President Royal College of Surgeons of England. He referred to the great services of Sir George in the war; to his very kindly relations to the hospital at Etaples with which so many of the Belfast Medical School were connected; to his judicious and convincing contributions to the Medical Society at Etaples; and to the charm and sympathy of his character, which endeared him to all who were fortunate enough to work under him. The Society had not many honours to bestow, but they asked his acceptance of their highest honour, of which they were somewhat jealous. There were only nine on the list, and in former times it contained such names as Lord Lister. Sir George Makins, in thanking the Society, referred to his indirect connexion with Belfast through the late Sir William MacCormac, whose dresser he had been, and with whom he worked for many years in close personal friendship, and at whose house he had met many Belfast people. He then gave his address on "Injuries to the heart." He referred to the experience in civil life and at the front during the war; to the dangers of shock, secondary infection, injury to valves and to the vital strands of muscle; the small amount of blood in the pericardial sac was astonishing. Illustrations were thrown on the screen of many specimens, and details given of many cases, as the "hydraulic explosion effect" in a full heart or the "burst paper bag." He then dealt with the symptoms and with the great difficulty of the interpretation of the curious and rare physical signs, such as the "tapping" sound, or click, supposed to denote a foreign body in or near the wall of the heart. In cases of injury to the heart, the diagnosis might be very simple or very difficult; the prognosis of operation on the actual heart was 50 per cent. mortality; higher figures were given. The indications for operation and the technique were referred to. Professor Sinclair proposed, and Dr. J. Walton Browne seconded, that the heartiest thanks be given to Sir George Makins for his most interesting and instructive address. This was passed by acclamation.

WOUNDED PERSONS IN DUBLIN HOSPITALS.

Notices have been served on the authorities of all Dublin hospitals requiring them to furnish daily to the military authorities a list of patients admitted suffering from

bullet wounds. The Crown forces can at present enter the hospitals at any time, day or night, and have been doing so. In the circumstances the hospital authorities consider it invidious to furnish the return required by the military. The following is the text of the Order:

To the Secretary, Hospital.

By virtue of the powers conferred on me under Regulation 53 of the Restoration of Order in Ireland, Regulation 1, the undersigned, being a Competent Military Authority under the said regulations, do hereby order you, the secretary, being the person in charge of the hospital, to furnish to me (in writing) the names and descriptions of all persons admitted to your hospital who are or are suspected to be suffering from wounds caused by bullets, gunfire, or other explosives, together with such particulars and information concerning them as may be within your knowledge. Such information is to be furnished by you daily to me at Headquarters, Dublin District, Lower Castle Yard, Dublin. Failure to comply with this order will render you liable to be proceeded against for an offence against the Restoration of Order in Ireland Regulations.

L. D. F. OLDMAN, Colonel Commandant,
Commanding Dublin District,
Competent Military Authority,
Lower Castle Yard, Dublin.

Mr. H. S. Meade, Surgeon to St. Vincent's Hospital, Dublin, has stated that the Order was dead against the etiquette of the profession, and has declined personally to make such reports. His surgical colleague, Mr. J. S. McArdle, in an interview reported in the *Freeman's Journal*, said that the order would indicate that the surgeons might betray confidences in their own hospitals, because it was only they, not the secretary, who could learn the particulars of any case placed under their care; he expressed the opinion that no power on earth would make Irish surgeons go back on the responsibilities which have grown with their advances to the higher walks of the profession. Dr. Sigerson, in an interview, recalled the fact that during the revolutions in Napoleon III's time the French hospitals refused to do what the Irish hospitals were now asked to do. The French hospitals refused to give the names of revolutionaries who were being treated.

Amongst the recent arrests by the Crown forces in Ireland are a number of medical practitioners, including Miss Ada English, M.D., assistant medical officer, District Asylum, Ballinasloe. Dr. James Ryan, who graduated in the National University in 1917, was arrested some months ago, and, so far, has not been brought before a court-martial.

England and Wales.

PAYING PATIENTS AT A LIVERPOOL POOR LAW INFIRMARY. From a communication made to the *Liverpool Courier* by Mr. Cleaver, clerk to the West Derby Union, we learn that a large number of paying patients have for several years been admitted to the hospitals in the West Derby Union, either as emergency cases, or because the patient could not obtain admission to a voluntary hospital or was unable to pay the charges of a private nursing home. Recently the committee of the Mill Road Infirmary received a letter from Dr. W. B. Bennett, chairman of the Liverpool Branch of the Middle Classes Union, asking that definite provision should be made for such patients. The board of guardians agreed on January 26th that as an experiment arrangements should be made for the admission to the infirmary of patients resident in the West Derby Union, either upon the recommendation of the patient's private medical attendant or upon personal application, subject to the discretion of the medical superintendent, who would have full power to grant or refuse admission. The arrangements provide for the admission of acute medical or surgical cases resident within the area of the union, either on the recommendation of their private medical practitioner or on the application of the patient or his friends. Such patients will pay three guineas a week, and their private medical attendant will be allowed to consult with the medical staff of the infirmary, but no interference will be allowed either in the treatment or nursing of such patients. The infirmary is administered by a medical superintendent, who is assisted by three resident medical officers; there is also a visiting staff, including a visiting surgeon, dermatologist, ophthalmic surgeon, and dental surgeon. It does not appear

how far these proposals accord with the wishes of the local practitioners, who may or may not regard them as valuable to the community, but they seem to differ considerably from any policy so far outlined by the British Medical Association.

PRESENTATION TO DR. BARTON, OF BLACKPOOL.

It had been felt for some time past by the medical practitioners of Blackpool and district that some tangible appreciation should be shown to Dr. H. T. Barton for his valuable services rendered to the profession locally for many years past. Dr. Barton has acted as secretary to the Local Medical Committee since the inception of the Insurance Act, and it is mainly due to his energy and his wide knowledge of the medical sections of the Act that the local practitioners have found insurance matters working so smoothly in this district. Dr. Barton also acted as secretary to the Local War Emergency Committee, and was of the greatest assistance to that committee also. With this object in view, a large number of medical men met at the Queen's Hydro, Blackpool, on December 15th last. After an excellent dinner, Dr. Godley (chairman) spoke of the esteem and regard with which Dr. Barton was held by the profession locally and of his untiring energy in the interests of the profession, of how he put aside his own work, often at great inconvenience, to serve the interests of an individual medical man or the profession generally. Nothing was too much trouble for him. When the interests of the profession were at stake, either in London or in a distant town, he would rush off to the meeting and report fully at the next local meeting. Dr. McIntosh, in presenting Dr. Barton with a handsome silver salver and a fitted dressing-case, spoke in felicitous terms of the great amount of work done by Dr. Barton for the profession.

ONODI COLLECTION OF NASAL ANATOMY.

THE Royal College of Surgeons of England have accepted the gift of this valuable collection from the Onodi Subscription Fund Committee. The specimens will be mounted and catalogued by the College, and when completed each subscriber will be presented with a catalogue.

The list of subscribers is as follows:

- £5 10s.—Honorary Staff Central London Ear, Nose and Throat Hospital.
 £26 5s.—Honorary Staff, Throat Hospital, Golden Square.
 £20.—Sir William Milligan.
 £10 10s.—Sir St. Clair Thomson, Sir James Dundas Grant.
 £10.—Messrs. Mark Howell, A. Logan Turner.
 £5 5s.—Sir John Bland Sutton, Sir F. Bell Loughurst, Messrs. W. M. Mollison, Norman Paterson, Somerville Hastings, W. Douglas Harmer, T. A. Rose, A. Brown Kelly, Tyrrell Grey, W. G. Howarth.
 £5.—Messrs. D. R. Patterson, Thelwall Thomas, A. J. Hutchison, Herbert Tilley, H. Lambert Lack.
 £3 3s.—Sir Charles Ballance, Sir Charles Ryall, Dr. William Hill.
 Messrs. Herbert J. Marriage, G. W. Wilkinson, J. F. O'Malley, A. L. Macleod, C. A. Parker, L. D. Davis, W. G. Spencer, W. Jobson Horne.
 £3.—Messrs. L. A. Peters, Charles J. Heath.
 £2 2s.—Sir William Arbuthnot Lane, Sir Frank Colyer, Sir Harold Stiles, Sir Anderson Critchett, Messrs. George Gathcart, W. S. Syme, Randall Pickard, W. H. Dolamore, H. Watson Turner, Albert A. Gray, Ernest Clarke, D. Treacher Collins, C. Ernest West, Dr. James Taylor, Mr. T. Guthrie, Sir G. Sims Woodhead, Dr. George Morgan, Dr. John Eyre, Dr. P. Watson-Williams, Messrs. W. H. Macmillan, Philip Franklin, Robert P. Mathers, H. J. Waring.
 £1 1s.—Mr. V. L. Sanzgiri, Dr. W. Ainslie Hollis, Messrs. William Appleyard, R. P. Rowlands, J. H. Badcock, Russell Barrett, Henry Peterkin, George E. Waugh, Wilfred Glegg, Sir D'Arcy Power, Messrs. H. O. Dickin, Henry Smurthwaite, Dr. Peter Macdonald.
 £1.—Messrs. Thomas Rogers, William Rushton.
 10s.—Mr. Andrew Ellis Wynter.
 5s.—Mr. George Jones.

In November 593 cases of plague occurred in Java, all of which were fatal, as compared with 637 in October.

THE Board of the Royal Salop Infirmary has adopted a resolution recording the irreparable loss sustained by the death of Mr. Arthur Jackson, who for nearly thirty years was honorary surgeon and subsequently honorary consulting surgeon to the Infirmary.

A SPECIAL post-graduate course, lasting two weeks and consisting of thirty lectures, will be held at Easter, commencing on March 21st, at the Medical Clinic, Hôtel-Dieu, Paris, on "Recent ideas on diseases of the liver (including the diseases of the biliary passages and the pancreas)." The fee is 150 francs, and particulars may be had from the Secretary of the Faculty of Medicine, University of Paris. Further post-graduate courses are, it is announced, to be carried on later in the year: in July, on diseases of the digestive system, and in September a practical course on the application of laboratory methods to diagnosis.

Correspondence.

"MINUTE BODIES" IN EPIDEMIC ENCEPHALITIS.

SIR,—With reference to Dr. C. Da Fano's interesting and suggestive "Preliminary note on the histo-pathology of epidemic (lethargic) encephalitis" in the JOURNAL of January 29th, 1921, I write to say that within the last few weeks, while studying the pathological histology of a series of cases of encephalitis, I have observed structures which appear to be identical with the "minute bodies" described by him. They were first noticed in sections stained by the Nissl method, and have been found in each of three cases of the series examined by this method. The remainder of the cases have not yet been investigated. The bodies were seen in the nerve cells of the pons, optic thalamus, mid-brain, cortex, and also in the interstitial tissue. They appear to occur in comparatively few cells and their detection requires systematic search. Their presence is associated with considerable degenerative changes, and I cannot recall observing them in cells of normal appearance.

In the main the appearances found agree with those described by Dr. Da Fano, though I have not met with such large numbers in a nerve cell as shown in his Fig. 1. Until reading his article I had formed no opinion as to the significance of these bodies, though I had come to the conclusion that they were morphologically distinct from the pigmentary granules commonly found in the nerve cells in encephalitis.—I am, etc.,

A. F. BERNARD SHAW,
Pathological Department, College of
Medicine, Newcastle-upon-Tyne.

January 30th.

WHAT IS A SYMPTOM?

SIR,—In his paper published in the JOURNAL of January 29th, Sir James Mackenzie discusses "The Relations of Symptoms to Disease."

All those who are following Sir James's valuable work—and they are many—will want to know what meaning he attaches to the term "symptom." I therefore venture to ask what precisely that meaning is.—I am, etc.,

HARRY CAMPBELL.
London, W., Jan. 29th.

THE PRODUCTION OF SYMPTOMS.

SIR,—As one who believes that Sir James Mackenzie, in enunciating, in the JOURNAL of January 29th, the law that the vast majority of the symptoms of disease are disturbances of normal reflexes, has done for medicine what John Dalton did for chemistry in 1803, I desire to draw attention to certain aspects of his theory in its relation to pulmonary tuberculosis. The symptoms of this disease are not only in harmony with Sir James's law, but also extend in some measure its application. In the fourth group of diseases, represented by "a confused heap of symptoms in which it is not possible to obtain a suggestion as to their relation to a common cause," Sir James Mackenzie places—

"all chronic diseases, even though the ill health is definitely due to damaged organs which can be recognized by physical signs—as arterio-sclerosis, chronic heart disease, chronic kidney disease, and even consumption and cancer. The reason for including these is that they are probably secondary diseases, the original cause not being capable of recognition."

As regards pulmonary tuberculosis, I presume that this sentence refers to the symptoms of the disease, and implies that these symptoms cannot be explained in relation to the morbid changes in the structure of the lung. Even if it be so, I submit that tuberculosis should not be included in this group. Many years ago I learnt from Sir Robert Philip that pulmonary tuberculosis is not a local disease of the lung, but is a general toxæmia affecting all systems of the body, and due to successful infection by the tubercle bacillus; and I now suggest that the symptoms of this disease may be explained by the effects of toxæmia on all reflex arcs of the body. Further, I submit that in this instance at all events it is not possible to differentiate between a stimulus acting on the receptor (A), and an agent altering the receptivity of the nervous mechanism (B) and the effector (C) of the symptom.

These propositions are easily illustrated. A very early symptom of pulmonary tuberculosis may be uneasy sensa-

tions in the stomach during digestion, associated with hypersensitiveness of the gastric mucosa—that is, of receptor (A) due to toxæmia. Later on, tuberculous toxins produce an irritability of the vagus nerve, and an entire reflex arc is affected. Food irritates the hypersensitive stomach (A), and this excites the vagus (B), with the result that the ingestion of food is followed by a reflex secretion of mucus in the respiratory tract (C). After meals the patient has coughing, hawking, and retching.

This symptom is explained by the increased irritability of a reflex arc, every portion of which is affected. Most probably it is but the exaggeration of a normal reflex whereby the ingestion of food is followed by an increased flow of saliva. Apart from tuberculosis, I have noted that when this reflex is even slightly exaggerated the area over which it operates is extended, and that there is an increased flow of secretion in the upper respiratory tract, particularly in the nasopharynx, and even from the lacrimal glands. Although the reflex arc in other symptoms of tuberculosis may not be apparent at present, many true things have been discovered by analogy, and the study of Sir James Mackenzie's law will certainly lead to the recognition of many reflexes hitherto unobserved.—I am, etc.,

London, S.W., Jan. 29th.

HALLIDAY SUTHERLAND.

TREATMENT OF THE PRE-OPERATIVE STAGE OF ENLARGED PROSTATE.

SIR,—I agree with Dr. MacMunn that there are cases with prostatic symptoms that do not require operation.

In the address to which he refers I did not set out to discuss all cases that might or might not require operation, and the only words which might convey this impression occur in a heading, "Indications for operation," that was slipped in after the typescript left my hands and was unnoticed by me in reading the proofs. The text below this, however, leaves no doubt that the only indications are those of operation as opposed to catheter life, and not the general question of indications for operation in enlarged prostate.

The theme that I developed, and that I hoped was clearly stated, was that all patients complaining of prostatic symptoms should be investigated, that the investigation should be thorough and should not be confined to the urinary tract, and that patients with enlarged prostate should not be allowed to drift into renal inefficiency from back pressure or urinary sepsis from catheterization.

I cannot see how Dr. MacMunn gets the impression that I wish to operate on all cases complaining of prostatic symptoms or on all cases where the prostate is at all enlarged provided they are fit to stand an operation. The majority of cases of enlarged prostate that I have observed have been steadily progressive in regard to the symptoms, or the ascertainable size of the prostate, or the effect on the urinary tract, or on all of these counts. There are cases in which the enlargement seems to stand still; and if this apparent arrest occurs at a period before the obstruction has produced residual urine, there is no harm, so far as the urinary tract is concerned, in waiting, provided the patient keeps under observation. But one remembers cases where the patient has received the assurance that the condition was stationary, and, in default of an increase or with only a small increase in the symptoms, has come up after some years for examination with a "silent" prostate, chronic distension of the bladder, and serious damage to the kidneys; or, on the other hand, the once simple enlargement now shows an area of hardness that leaves no doubt as to a malignant change.

I have asked for nothing more than that these possibilities be placed before the patient, and he should make his own decision. He has in any case the right to know that such eventualities may occur.

In regard to nocturnal frequency after the age of 50, I think if Dr. MacMunn will read this paragraph again, he will see that I recommend that such cases should be investigated, not that they should be operated on because they have this increased frequency.

I am sure Dr. MacMunn does investigate these cases, for he has evolved a theory to explain the symptom. I do not doubt that in his investigation he finds a good many cases which he would classify under some other heading than "waning of the vesical sphincter."—I am, etc.,

London, W., Jan. 25th.

J. W. THOMSON WALKER.

SIR,—Mr. Thomson Walker's important contribution in the JOURNAL of January 15th emphasized the possibility of avoiding various special risks. Mr. MacMunn's letter in your issue of January 22nd very properly goes a stage further back, and raises the most important question of all, *What can be done to diminish the number of cases requiring operation?*

Do we know the cause of the enlargement? Certainly a large proportion of those cases coming to us for operation are adenomatous. Is there a gradual failure of balance of internal secretion as old age comes on? Is there any material evidence in favour of the use of orchitectracts to combat senile prostatic enlargement? Can anything effective be done by bladder hygiene and the voluntary, thorough, regular emptying of the organ? Chronic inflammatory enlargement may respond to massage; but adenomatous hypertrophy can hardly be expected to do so.

What influence has diet? In Kashmir the Hindus, who are vegetarians, enjoy a remarkable immunity from enlarged prostate. In the Mohammedans, who are meat eaters, prostatic trouble is not rare. In advanced cases with persistent retention I have frequently operated, with the usual beneficial rejuvenating result. But how many successful cases are to be weighed in the balance against one death, whether from embolism or other cause? It is true that the results would be greatly improved if we operated before catheter life had begun. All surgeons of experience, however, know that many cases do recover after a period of catheterization and live in comfort to a good old age. Few would therefore advise routine operation after a first attack of retention.

Prostatectomy has won an honoured place in surgery, due in no small measure to the work of Sir Peter Freyer, Mr. Thomson Walker, and other distinguished surgeons. A still greater advance will be made when we know with more precision how to arrest the enlargement of the prostate before it produces serious results. The disease is all too common. Is it too much to hope that some of your readers may be able to contribute to our knowledge in this respect?—I am, etc.,

Bromley, Kent, January 30th.

ERNEST F. NEVE.

THE PREVENTION OF VENEREAL DISEASE.

SIR,—The dispute which is being waged in these pages on the subject of prophylaxis in venereal disease has long ago lost the characteristics of a scientific discussion, and is rapidly acquiring those of a family quarrel. What is more distressing still is the fact that this quarrel has spread beyond the confines of the medical into the lay press, so that the noise and clamour of it are plainly heard by the man in the street. Small wonder that the latter has shrugged his shoulders and lost his confidence in those to whom he is entitled to look for leadership and advice.

Has not the time come for emphasizing points of agreement rather than those of dispute? Two societies exist for the purpose of combating venereal disease—the National Council for Combating Venereal Diseases and the Society for the Prevention of Venereal Disease. On their lists of membership appear names that command respect and consideration for the opinions that each society has advanced. No one who has seen the excellent work achieved by the National Council for Combating Venereal Diseases can consider it an *efete* body that has sacrificed every practical measure to a sentimental fetish. No one who has read the list of membership of the Society for the Prevention of Venereal Disease can suppose for one moment that such eminent men would deliberately support a policy that is calculated to undermine the moral welfare of the community. In spite of the noise and dust raised by various extremists, it is certain that there exists a considerable sphere of activity common to both societies.

It is only over the question of prophylaxis that the split has arisen. The Society for the Prevention of Venereal Disease is convinced that the packet system has been instrumental in materially reducing the incidence of venereal disease in the services, and believes that its adoption by the civil community would be equally productive of good. The National Council for Combating Venereal Diseases, on the other hand, is dissatisfied with the results of prophylaxis in the services, and does not in any case believe that the adoption of the packet would be productive of

good when applied to the civil community. Each of the societies has put forward statistics upon which the other has cast doubts, and each has arrived at conclusions which are endorsed by experienced authorities. Where does the truth lie? It is difficult, or impossible, at the moment to say. Statistics can be found to prove or disprove most of our prejudices, and our attitude towards the question of "packets for the people" must for the present be based on personal opinion rather than established fact. The centre of truth, like the centre of gravity, lies somewhere between the two extremes. It is possible that the National Council for Combating Venereal Diseases has underrated the importance of prophylaxis in the campaign against venereal disease. It is equally possible that the Society for the Prevention of Venereal Disease in its enthusiasm for a neglected remedy has tended to regard it as the "single measure that will cure our ills."

There is work for all in the campaign against venereal disease. The National Council for Combating Venereal Diseases is doing yeoman service in its educational campaign, and in its agitation for the provision of free and adequate treatment for venereal disease throughout the world. The Society for the Prevention of Venereal Disease is convinced of the success of prophylaxis in the army and believes that its extension to the civil population will be equally effective of good. A campaign in favour of packets is the logical outcome of these views.

Let each of the societies work along the line it has chosen, but let it be recognized that until further data are available it is upon personal opinion rather than upon verified fact that conclusions must rest.

Lastly, may I put forward a suggestion that has already been made? Is it asking too much that members of the two societies should arrange to meet? Surely it is better that differences of opinion should be amicably discussed in a meeting of medical men rather than be made the subject of a bitter and somewhat tedious correspondence in the press. I believe that if such a meeting could be arranged a vast amount of common ground would be found to exist between the two societies, and that a satisfactory working agreement could be arrived at on this thorny subject of prophylaxis.

Apologizing for trespassing on your valuable space, I am, etc.,

London, W.1, Jan. 26th.

KENNETH M. WALKER.

SIR,—Mr. E. B. Turner is not backward in taking advantage of his position of reviewer of Sir Archdall Reid's book to deliver an attack upon those with whom he does not happen to agree. He emphasizes the time-worn fallacy that the sexual instinct can be suppressed by terrorism. He has such a poor opinion of that portion of his fellow countrymen whom he calls "the populace" that he thinks that if it is entrusted with the ripe knowledge of such a practical authority as Sir Archdall Reid, fornication will be more practised than ever. He ignores the fact that in spite of his own lectures venereal disease is still rampant, and he has nothing to suggest but to persevere in a policy which is a proved failure.

It is interesting to note that he admits that many people will be protected by prevention; but he is of opinion that knowledge of self-disinfection will increase promiscuous sexual indulgence. This cannot be proved. But the admission and the opinion disclose the frame of mind, which is the real centre of the opposition to the teachings of science. It is the frame of mind that would apparently prefer that the many who would be protected should be visited with venereal disease rather than face the possibility that a certain number of people might gratify the sexual instinct who might otherwise have abstained.

Your readers must be aware of the cleavage between the two schools of thought. The one school would deny knowledge to their fellow countrymen; the other would give them access to it. Mr. Turner seems to think that knowledge ought to be and can be concealed from "the populace" by a policy of suppression. Other of your correspondents would appear to think that science can be defeated by ridicule.

The Society for the Prevention of Venereal Disease stands for access to knowledge. This knowledge is already public property. It cannot be suppressed. It is the duty of the State to see that it is scientifically applied, and we

believe that our fellow countrymen have enough intelligence and self-control to be entrusted with it.—I am, Sir, your obedient servant,

London, W., Jan. 31st.

WILLOUGHBY DE BROKE.

* * In a further letter, written on behalf of the Executive Committee of the Society of which Lord Willoughby de Broke is president, Dr. H. Wansey Bayly wishes to point out that Mr. E. B. Turner's review of Sir Archdall Reid's book, printed in our last issue, "must not be taken as an impartial review by an unbiassed reviewer outside the sphere of the controversy." Where such a person is to be found we do not know. As many of our readers are well aware, Mr. Turner is the representative of the British Medical Association upon the National Council for Combating Venereal Diseases, and his personal position in the present controversy is made sufficiently plain in the course of his review.

SIR,—In Mr. Turner's review of Sir Archdall Reid's book, he says:

Miss Ettie Rout, a member of the Grand Committee of the Society for the Prevention of Venereal Disease, crystallizes the policy of that society in the following words, quoted by the Archbishop of Canterbury in the debate in the House of Lords "Every boy and girl in our parishes must be provided free with the outfit which will make them secure, and when you have done that all will be right—go with clean people and you will be clean."

Please permit me to explain that these words were never said or written by myself. They were misquoted in the first instance in the House of Lords by the Archbishop of Canterbury and repeated in Sir Archdall Reid's book, from which Mr. Turner has quoted between inverted commas.—I am, etc.,

London, W., Feb. 1st.

ETTIE A. ROUT.

THE BRADFORD MUNICIPAL HOSPITAL.

SIR,—Dr. Slater finds fault with my term, "obsolete buildings." I am quite willing to amend it by substituting the phrase "a group of buildings unsuitable for the requirements of a general hospital." We can leave the old blocks out of the argument altogether, and inquire into the justification of my criticism when applied to the newer buildings. Dr. Slater speaks of the modern hospital buildings built sixteen years ago. He describes the wards as providing accommodation for 156 adults, and as "comparing favourably with any in the country." Nevertheless he has declined my challenge to him in the local press. I suggested that one of these wards should be measured by me, and if it provided anything near 1,500 cubic feet a bed and 125 square feet of floor space, I would forfeit £5 and apologize. I knew he would decline, because these wards were built for Poor Law purposes under the Poor Law Regulations. The cubic space per bed is roughly 1,050 feet, and the floor space about 85 square feet. No one with any practical knowledge would suggest that such an allowance is adequate for general hospital purposes.

Dr. Slater also states that "within the last four years three other pavilions have been erected and put into use, each accommodating 100 patients." We are led to believe that these are part of "St. Luke's, with its splendid wards and equipment." As a matter of fact, these three "pavilions" are nothing more than some temporary emergency structures of wood and brick which were put up for soldiers during the war. A hundred soldiers could be accommodated in one of these "pavilions" by putting a row down each side and a row up the middle. Does Dr. Slater really think these are hospital wards capable of accommodating 300 patients? I leave it to your readers to decide.

In conclusion, may I say that Dr. Slater totally misunderstands my feelings in the matter? Everyone knows that Bradford requires a good first-class hospital. The Royal Infirmary Board has already gone some way towards establishing one—in fact, some building operations have actually commenced upon the new site. Such proposals of the Health Committee, however, will put such a burden on the rates that the new infirmary scheme must inevitably die of inanition. I should not greatly regret it, provided the Health Committee had a good substitute to offer in its place. They have nothing of the kind. The municipal hospital cannot be made into an institution worthy of the city merely by talking about "splendid wards comparable with any in the country."

When I spoke of co-operation in my first letter I had in mind a genuine combination of effort to complete a new infirmary as soon as possible under a sound policy in which voluntary and municipal support were combined. It could be done if only the various interested parties would determine to bury all antagonism and unite to give the city what it really wants.—I am, etc.,

Bradford, Jan. 31st.

J. BASIL HALL.

RISKS AFTER OPERATIONS ON TONSILS AND ADENOIDS IN OUTDOOR CLINICS.

Sir,—I have been interested in reading the recent correspondence on this subject, especially as several leading surgeons have confirmed the opinion which I have held for some time—that these operations should not be undertaken by hospital authorities unless they are prepared to treat the children as in-patients.

With reference to Dr. Watson-Williams's remark that "We have been waiting year after year for something to turn up" with regard to further hospital accommodation for these patients, I should like to draw his attention to the manner in which these requirements are met in Leicester to-day. Two years ago I pointed out to the City of Leicester Education Committee that children suffering from enlarged tonsils and adenoids could be much more safely and effectively treated if they were kept in hospital for at least twenty-four hours after the operation than by discharging them on the same day, as was being done at that time. Since further accommodation at the hospital where these cases were being treated could not be entertained, I recommended that the education authority should establish a central school clinic, including a suitable operating theatre, and a ward containing twelve beds for the specific purpose of treating these defects. With the consent of the Ministry of Health this recommendation has now become an accomplished fact.

Previously these cases were treated at a local hospital, the arrangements being that the school surgeon should have the use of a small operating theatre three mornings each week, and that patients should be provided with beds for the day, under the supervision of a school nurse. The children were usually discharged in the evening, but in very exceptional cases a child might be kept in for the night at an additional charge. The following day, and on subsequent days if necessary, the school nurse visited the patient and noted if there was any rise in temperature or other symptoms to be reported to the surgeon. Over three thousand children have been treated in this way during the last few years. Although no serious complications have arisen, it is obvious that sending children so soon after the operation to homes that are often dirty and overcrowded, and where there is no skilled nursing, must be prejudicial to the rapid recovery of the patients.

Under our present scheme the children are kept in bed for at least twenty-four hours after the operation, and, if it is thought advisable, they can be kept longer.

From the inception of the school clinics in Leicester it has been the practice to refuse treatment entirely to any patient whose relatives could afford to pay an ordinary medical fee, whilst those who could pay a small fee have been charged in proportion to their income, and only those who were unable to pay anything have received free treatment. The following details showing the steps that must be taken to obtain treatment may be of interest:

1. The school medical officer must notify the parent that the defect exists.
2. The parent must sign a printed application form for treatment at the school clinic.
3. An investigator visits the home and records the number of persons in the family, the number of persons in work, and the addresses of their employers.
4. The amount of wages earned by each worker in the previous three months is obtained direct from the employer.
5. By means of a scale sanctioned by the Medical Service Committee, it is decided whether the case is to be refused, to be treated at a price according to income, or to receive free treatment.
6. If it is decided that the patient is to be treated, an appointment is made for a consultation with the surgeon, who determines if an operation is necessary.
7. A further appointment is made for the operation, and the parents are instructed how to treat the patient before and after the operation, by means of a printed leaflet.
8. The operation is performed, and the child remains in hospital for twenty-four hours.
9. The school nurse visits the patient the day after he has returned home.

10. Ten days later the patient is seen by the surgeon, who gives instructions with regard to breathing exercises, etc.

—I am, etc.,

Leicester, Jan. 25th.

ALLAN WARNER,
School Medical Officer.

Sir,—It is strange that in all this discussion on the risks of these operations, whether on the table or for lack of after-care, no one has suggested an alternative. There is in many cases such an alternative: I well remember demonstrating a complete cure by medicinal treatment in a case which had been taken to a consultant, "for an independent opinion" behind my back. He wrote to me to ask me to arrange for (the third) operation for removal. But with medicine they completely disappeared, and have given no sign for seven years.

In those cases which come on acutely—as, for example, after scarlet fever—or, at any rate, grow rapidly and exuberantly, it is my experience that iodine, either as tincture of iodine or as iodide, is infallible. It cures. Of the chronic cases, I find in the majority that nose breathing, with a little training as accompaniment, is generally rapidly restored by that drug. So, too, with the hearing. I have at this moment a child under observation with pronounced adenoids, and—so far—one operation, who has in a fortnight ceased to snore, and almost completely lost a deafness which has lasted the greater part of a year.

The effect is so striking that I have come to believe it wrong to subject a child to operation until it has had a fair trial of treatment with iodine in some form. If operation turns out to be necessary after all, it will be found to be much easier, more effectual and less bloody, by reason of the preliminary treatment.

For some reason I do not find enlargements of the tonsils to disappear so satisfactorily as the adenoids. But the tonsils nearly always shrink in size; they nearly always alter in texture; and, even if they have not been reduced to normal dimensions, the child loses the excessive sensitiveness to infective processes which is the worst feature of chronic tonsillitis. And, when necessary, the operation is much easier and much less bloody. The dosage is, of course, in proportion to age. I generally begin with m_j of tr. iodi, or gr. ij of sodium iodide, well diluted, thrice daily, and gradually increase the dose where necessary.—I am, etc.,

Rayleigh, Essex, Jan. 30th.

B. G. M. BASSETT.

Sir,—I write to support Mr. Fry in the views he holds with regard to the operation for the removal of tonsils and adenoids. For upwards of twenty years I operated upon these cases in the out-patient department of the Bedford County Hospital; I never sent a case into hospital on account of hæmorrhage or sepsis during this period, nor has any patient developed complications. Experience is the final court of appeal.—I am, etc.,

Bedford, Jan. 30th.

S. J. ROSS.

HEMICOLECTOMY.

Sir,—In Mr. Sheen's article "On the end-results of colectomies for intestinal stasis," in the *JOURNAL* of January 22nd, p. 116, he asks: "Is there nothing besides the belt and paraffin but complete colectomy?" I would answer, "Among other things, hemicolectomy." I have done this operation (as described in the *British Journal of Surgery* for 1915) just a dozen times, and it seems to me that the risk is little, if any, more than that of the colectomy devised by Mr. Waugh, and in some cases it is a more suitable operation. All my patients recovered quickly without any complication; the only case in which there was not complete primary union was one in which cholecystostomy was done at the same time. One point in which hemicolectomy differs very much from complete colectomy is that the small bowel is not exposed in the former operation; the last few inches of the ileum are all that need be seen. There is therefore little risk of troublesome adhesions.—I am, etc.,

Belton, Jan. 27th.

R. D. MOTHERSOLE.

GLANDULAR AND PULMONARY TUBERCULOSIS.

Sir,—Dr. W. Williams, in his memorandum on the above named subject in your issue of January 29th, has touched on a matter of great interest and some importance.

Stanley Griffiths has concluded that there is some relation between attenuation of the virulence of the tubercle bacillus and the proximity of the lesion to the surface of the body, but I think that the actual suppuration of the gland has a great deal to do with the immunity of the subject against pulmonary tuberculosis. The tonsils are regarded as one of the first lines of defence against the tubercle bacillus, and are commonly the site of tuberculous lesions, but in a large series of bacteriologically verified cases of pulmonary tuberculosis I have noticed that there is practically never any enlargement of these glands. In the few cases in which some enlargement has been noticeable it has only been slight. If other tuberculosis and school medical officers have had similar experiences they would form a strong argument against the indiscriminate removal of the tonsils.—I am, etc.,

Newcastle-upon-Tyne, Jan. 31st.

W. H. DICKINSON,
Tuberculosis Medical Officer.

Universities and Colleges.

UNIVERSITY OF OXFORD.

Certificate in Practical Ophthalmology.

THE Board of the Faculty of Medicine gives notice that in and after Michaelmas term, 1921, candidates for the Final B.M. Examination will be required to submit a certificate of attendance at a course of practical instruction in ophthalmology, which included not less than twenty meetings during a period of three months, at an ophthalmic clinic recognized by the Board.

A decree was passed in Congregation on January 25th authorizing the continuance of the stipend of a woman demonstrator in the Department of Human Anatomy.

UNIVERSITY OF CAMBRIDGE.

The M.Ch. Degree.—On January 27th Mr. G. E. Wherry, on behalf of the Special Board for Medicine, brought forward a report containing proposals for raising the dignity and status of Masters of Surgery, of whom there are now only 27. He recalled the fact that until the late war this coveted degree was known by the distinctive initials "M.C.," which were then changed to "M.Ch.," in order to avoid confusion with recipients of the Military Cross. It was felt that some compensation was due to these distinguished surgeons and teachers, and the suggestion had been made that a Doctorate of Surgery should be set up. The Regius Professor of Physic, Sir Clifford Allbutt, emphasized the searching nature of the examination for the M.Ch. degree, remarking that it was exceeded in severity by the examination for no other university degree. Pending the establishment of a Doctorate, he felt that a genuine grievance might be met by revising the order of precedence in the interests of holders of the M.Ch. degree and by granting them special academic dress. At present Masters of Surgery rank in the order of presentation for degrees after Doctors in all faculties, and after Bachelors of Divinity, Masters of Arts, and Masters of Law; they wear the gown and hood of M.A.'s.

Readership in Experimental Psychology.—A Congregation held on January 28th approved the recommendation of the General Board of Studies that Dr. C. S. Myers, F.R.S., who for the past fourteen years has been University Lecturer in Experimental Psychology, should be appointed University Reader in that subject for a period of five years. With this appointment the University Readership lapses.

The following medical degrees have been conferred:

M.B., B.Ch.—P. Lazarus-Barlow, E. B. Verney.
M.B.—E. P. Hicks.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

An ordinary Comitia of the Royal College of Physicians was held on January 27th, with the President, Sir Norman Moore, in the chair.

The following were admitted to the membership of the College:

John Maurice Hardman Campbell, M.B.Oxon., James Henry Dible, M.B.Glasg., Maurice Gilbert Hanuay, M.D.Brux., L.R.C.P., Bernard Hart, M.D.Lond., L.R.C.P., Frederick Greig Hobson, M.B.Oxon., L.R.C.P., Charlotte Alice King, M.D.Lond., Douglas McAlpine, M.B.Glasg., William Edward Robinson, M.D.Oxon., L.R.C.P., Matthew Sidney Thomson, M.B.Camb., L.R.C.P., William Wragham, M.D.Lond., L.R.C.P.

Jointly with the Royal College of Surgeons, diplomas in (a) public health, (b) tropical medicine and hygiene, (c) psychological medicine, (d) ophthalmic medicine and surgery were granted to the successful candidates.

Dr. A. P. Beddard, Dr. A. J. Hall, Dr. J. W. Russell, Dr. F. Gowland Hopkins, were elected, on the nomination of the Council, councillors to take the place of Dr. Hamer, Dr. Voelcker, Sir Percival Horton-Smith-Hartley, and Dr. Caiger, who retired by rotation.

The President announced that he had appointed Dr. Herbert Spencer to deliver the Harveyian Oration and Dr. Michael Graham the Bradshaw Lecture in 1921, and that the Council has appointed Dr. Major Greenwood to deliver the Milroy Lectures in 1922.

A report dated January 4th, 1921, from Sir Humphry Rolleston

and Dr. R. O. Moon, representatives of the College at the celebration of the Centenary of the Académie de Médecine of Paris, held December 20th-22nd, 1920, was received. A medal of Médecine was offered by him to the Académie de Médecine, and the gift was accepted, and the gift was to him.

A report from the General Medical Council, on the session held in November, 1920, was the minutes.

After some formal College business the President dissolved the Comitia.

Diplomas.

Diplomas in the subjects indicated were granted in conjunction with the Royal College of Surgeons of England to the following candidates:

PUBLIC HEALTH.—P. F. Alderson, Madeleine S. Baker, T. B. Batchelor, W. W. Boyce, J. W. Caton, H. W. Catto, K. Comyn, T. A. Fuller, K. A. Gandhi, D. N. Gore, A. J. B. Griffin, P. F. E. T. Holden, P. G. Horsburgh, Lawder, J. T. Macnab, A. N. Martin, J. S. Ranson, H. J. Si. A. S. Wakely, A. Woolcombe.

TROPICAL MEDICINE AND HYGIENE.—G. V. Allen, J. Anderson, S. C. Basu, C. J. Caddick, W. B. A. K. Cullen, A. Dasgupta, A. A. Denham, A. M. El-Kirdany, Penstall, L. C. D. Hermitte, P. Y. Liang, R. H. Liscombe, A. R. Mo Parker, A. H. Patel, Evelyn B. Sa dram, W. R. Taylor, A. S. Westmott.

OPHTHALMIC MEDICINE AND SURGERY.—J. R. Anderson, R. S. Candlish, K. M. Labiebe, W. O. Lodge, B. H. Pestilaka, S. A. Rahim, G. Zachariah.

PSYCHOLOGICAL MEDICINE.—M. Dia, E. D. T. Hayes, O. S. Martin, H. W. Parnis.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

THE Hunterian Oration will be delivered in the theatre of the College by Sir Charters J. Symonds, K.B.E., C.B., on Monday, February 14th, at 4 p.m.

The Arris and Gale Lecture on the cause and prevention of myopia will be delivered on Wednesday, February 16th, at 5 p.m., by Dr. F. W. Edridge-Green, C.B.E., F.R.C.S.

A Hunterian Lecture on a research into the pathology and etiology of loose bodies composed of cartilage or of cartilage and bone occurring in joints will be delivered on Friday, February 11th, at 5 p.m., by Mr. A. G. Timbrell Fisher, M.C., M.B., F.R.C.S.

Two Hunterian Lectures on the surgery of the peripheral nerve injuries of warfare will be delivered by Mr. Harry Platt, M.S., F.R.C.S., on Monday, February 7th, and on Wednesday, February 9th, at 5 p.m.

CONJOINT BOARD IN SCOTLAND.

THE following candidates have been approved at the examination indicated:

FINAL EXAMIN.—*Medicine and Surgery:* D. J. H. Ferdinando, Figgdor, R. E. Hopton, J. B. O'Neill, H. Peries, G. ap V. Jones, *Surgery:* J. Murray, J. S. A. Rogers, J. M. McDonald, *Medical Jurisprudence and Public Health:* W. A. McK. Gibson, J. H. Dobbin, C. T. Williams, Marguerite M. I. Swanson, P. J. D. Dyce, J. Readie, R. L. O'Keefe, P. I. Malloch, Marjory J. A. Ogilvie, A. G. Thom, A. R. Lambie, T. Kelarkun, D. R. Cilliers, J. A. H. Dyles, E. J. Sykes, T. P. Kelly.

The following candidates were admitted L.R.C.P.E., L.R.C.S.E., L.R.F.P. and S.G.:

R. A. Cooper, F. J. D. Cass, G. J. D. Hammond, G. J. Murray, J. Shulman, J. H. Wilson, A. Cuthbertson, M. H. Carleton, H. G. Fitz-Maurice, A. T. Caddell, P. Parthasarathy, W. G. Carew, J. Black, A. Tirumalaia, P. M. Fernando, J. B. van Cuylenburg.

Obituary.

WILLIAM L. ROBERTSON, M.C., M.B., Ch.B., F.R.C.S.Ed., Surgeon, Dundee Royal Infirmary.

WE much regret to announce that Mr. William L. Robertson, M.C., of Dundee, died on January 24th in his 39th year, from septic poisoning due to a needle prick, during the performance of an operation at the Royal Infirmary.

After graduating M.A. at St. Andrews University he proceeded to Edinburgh University, where he took the degrees of M.B., Ch.B. in 1905; he obtained the diploma of F.R.C.S.Edin. in 1907. After serving as resident surgeon at the Edinburgh Royal Infirmary, the Chalmers Hospital, and the Hospital for Sick Children, Edinburgh, he became honorary assistant surgeon at the Dundee Royal Infirmary, and subsequently clinical tutor at University College, Dundee. Mr. Robertson, who was a captain in the 3rd Highland Field Ambulance, went to France with that unit in 1914, and later received a staff appointment in the 51st Division. He was twice mentioned in dispatches, and was awarded the Military Cross. On being transferred to the Italian front he was appointed to No. 24 Clearing Station, and later given command of No. 70 Field Ambulance; he terminated his work on that section

as A.D.M.S. At the conclusion of the war he was appointed a surgeon at the Orthopaedic Hospital at Bangour, and on returning to practice at Dundee was appointed full surgeon to the Infirmary and to the orthopaedic annexe. In December last he was appointed lecturer in clinical surgery at St. Andrews University, and succeeded Mr. D.M. Groig as surgeon to the Victoria Hospital.

Mr. Robertson's death, after only three days' illness, came as a great shock to his many friends and to the profession in the East of Scotland. He was a man of outstanding ability, absolute honesty and of a most lovable disposition. Ever ready to help, he combined a convincing manner with a most modest estimate of himself. The loss sustained by the medical profession in Dundee cannot at present be realized.

The Services.

HONOURS.

FOREIGN DECORATIONS.

The King of the Belgians has conferred the Croix Civique, 1st Class, on officers for distinguished services rendered during the campaign: Major Maret, R.A.M.C., Captain ... and Captain Frederick ...

The name of Captain J. A. O'Driscoll, R.A.M.C., has been brought to the notice of the Secretary of State for War for valuable and distinguished services rendered with the British Military Mission in Siberia.

DEATHS IN THE SERVICES.

COLONEL OCTAVIUS TODD, C.B.E., A.M.S. (retired), died at Southsea on October 18th, 1920, aged 68. He was born in India, educated at Aberdeen, where he graduated M.B. and C.M. in 1878, and entered the army as surgeon on March 6th, 1880, attaining the rank of lieutenant-colonel after twenty years' service, and that of colonel on April 4th, 1906; he retired on July 1st, 1909. He served in the South African war, 1900-1902, and held the temporary rank of colonel while serving as P.M.O. of a division of the field force from May 2nd, 1900. He took part in the relief of Ladysmith, the actions at Vaal Krantz, Tugela Heights, and Pieter's Hill; operations in Natal, including action at Laing's Nek; and operations in the Transvaal; was four times mentioned in dispatches, in Sir Redvers Buller's dispatches of June 19th and November 9th, 1900, and in the *London Gazette* of February 8th, 1901, and July 29th, 1902; and received the Queen's medal with five clasps and the King's medal with two clasps. During the recent war of 1914-18 he was re-employed in England, and received the C.B.E. on June 3rd, 1919.

Medical News.

THE first meeting of the newly formed Brooklyn Cardio-logical Society was held recently under the chairmanship of the president, Dr. William J. Cruikshank. Among the honorary members are Dr. Thomas Lewis, F.R.S., London, Sir James Mackenzie, F.R.S., Aberdeen, and Dr. W. T. Ritchie, Edinburgh.

A SPECIAL course of lectures on fevers, their clinical and epidemic features, and measures for their prevention and treatment, will be given at Charing Cross Hospital Medical School by Dr. William Hunter, C.B., on Thursdays, February 10th, 17th, and 24th and March 3rd and 10th at 4.30 p.m. The lectures are free to medical practitioners and students of medicine.

DR. F. D. WYNN, M.O.H. for Wigan, has been appointed M.O.H. for Sheffield, in succession to Dr. Scurfield. He has devoted himself to public health work, and during the war was Divisional Sanitary Officer of the Egyptian Expeditionary Force. For a number of years he was honorary secretary and representative of the Leigh Division of the British Medical Association, and was intimately connected with the fine and successful fight the local profession put up for recognition in the matter of the staffing and working of the local hospital.

THE anniversary dinner of the Medical Society of London will be held at the Wharfedale Rooms, Hotel Great Central, on Tuesday, March 8th, at 7.30 o'clock.

A LECTURE on "The Innervation of striped muscle fibres and Langley's receptive substance" will be given at the rooms of the Royal Society of Medicine (1, Wimpole Street, W.1) by Professor J. Boeke, of Utrecht, at 5 p.m. on Wednesday, February 16th, with Professor Bayliss in the chair. Four other Dutch lecturers will also give one lecture each in English; particulars will be announced later. Admission free, without ticket.

WE are asked to draw the attention of all medical practitioners and of hospital authorities to a woman calling herself Margaret Crawford, M.B., Ch.B. Leeds (or Margaret de Laney Williams), whose arrest is sought on a warrant by the metropolitan police for alleged offences against the Medical Act, 1858. It is possible that this woman will seek admission to some hospital or infirmary for the purpose of obtaining instruction in midwifery; and it is requested that any information concerning her should be communicated at once to the local police.

THE Hunterian Society annual oration will be delivered by Dr. H. H. Bashford, on "The ideal element in medicine," on Wednesday, February 16th, at 9 p.m., at the Slon College, Embankment, E.C. All members of the medical profession are invited to attend.

SIR NAPIER BURNETT, K.B.E., M.D., has been appointed a Knight of Grace in the Order of St. John of Jerusalem.

A SPECIAL course in ophthalmology, for graduates and advanced students, is being arranged to be carried on daily during May and June at the Hôtel-Dieu Hospital, Paris, under the direction of Professor F. de Lapersonne, assisted by a staff of specialists in different branches. The course will include clinical examinations, practical (operative) work, and laboratory work, and a special certificate will be issued by the Faculty of Medicine at the end of the course. The number taking the course will be limited to forty, the fee is 150 francs (approximately £3 at present), and intending members should write as soon as possible to the Secretary of the Faculty of Medicine, Paris.

A GENERAL meeting of the Medical Officers of Schools Association will be held at 11, Chandos Street, Cavendish Square, W.1, on Tuesday, February 15th, at 4.45 p.m., when a paper will be read by Dr. E. H. T. Nash on "School punishments."

DR. WILLIAM BENTLEY PURCHASE, M.C., has been appointed deputy coroner for the Eastern District of London.

THE second annual 19th Casualty Clearing Station dinner will be held on February 19th at the Refectory Restaurant, Golders Green, London, N.W. Those wishing to be present are asked to communicate with the Rev. E. C. Doddrell, 6, Alexandra House, Regent's Park Road, Finchley, N.3. The price of tickets is 15s.

THE second International Congress of Eugenics will be held in New York City from September 22nd to 28th. The Honorary President is Dr. Alexander Graham Bell, and the President Mr. H. F. Osborn. The Secretary-General is Dr. C. C. Little, American Museum of Natural History, New York City.

AS a result of the Peace Commemoration Appeal, St. Bartholomew's Hospital has received upwards of £132,000. The Governors have passed a resolution of thanks to Mr. A. F. Shepherd, who originated and organized the appeal.

A MEETING of members of the medical profession to discuss the advance of medical education in China will be held on Monday, February 21st, at 5.30 p.m., in the Barnes Hall, Royal Society of Medicine, 1, Wimpole Street, W.1. Among those who will be present are the Right Hon. Sir Clifford Allbutt, Sir Donald MacAlister, Sir Alfred Pearce Gould, and Sir Francis Champneys.

AT the meeting of the Royal Anthropological Institute, at 50, Great Russell Street, W.C.1, on Tuesday, February 8th, at 8.15 p.m., a lecture (with lantern illustrations) on tailed men will be given by Professor Arthur Keith, F.R.S.

DR. C. CHAPMAN GIBBS, on his appointment as consulting physician to the National Hospital for Diseases of the Heart, after twenty-three years' service as physician, has been presented by his colleagues on the staff with a silver salver, in token of their appreciation of his work. The out-patients also presented him with a silver salver.

THE municipality of Bucharest has changed the name of one of its streets in honour of Dr. J. Clunet, the French physician, who for several years took an active part in combating epidemic disease in Rumania.

PROFESSOR LUIGI CONCETTI, editor of the *Rivista di Clinica Pediatrica*, and a well known authority on children's diseases, has recently died. His successor in the chair of children's diseases in the University of Rome is Dr. F. Lozzatti.

THE *American Journal of Obstetrics and Diseases of Children*, which discontinued publication in February, 1920, has been succeeded by the *American Journal of Obstetrics and Gynaecology*, the first number of which appeared in November.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are sent to the BRITISH MEDICAL JOURNAL alone.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Aitology, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, Medisecr., Westrand, London; telephone, 2630, Gerrard. The address of the British Medical Association is 429, Strand, London, W.C.2. The telegraphic address of the British Medical Association is 429, Strand, London, W.C.2. The telegraphic address of the British Medical Association is 429, Strand, London, W.C.2.

QUERIES AND ANSWERS.

INCOME TAX.

"DOUBTFUL" and his wife have been separately assessed for the income from their respective medical posts. "Doubtful" has had the married allowance of £225 and his wife the £45 special allowance for the earned income of a married woman. Is this, he asks, correct?

As regards the total allowance, yes; the right of separate assessment does not carry with it a right to any additional allowance. It would, however, have been more in accordance with strict law if the total allowance of (£225 + £45 =) £270 had been divided between husband and wife in proportion to their respective total assessable incomes—and the same division should apply to the £225, taxable at 3s. in the £.

"DILATED PUPILS."

DR. ERNEST KINGSCOTE (London) writes: In reply to "C. F. R.'s" letter in your last issue, I saw a patient, a girl, aged 22, who suffered from dilated pupils with severe headache after reading with suitable glasses. There was no ascertainable cause. The untoward symptoms were relieved by electro-vibration on the centre of the forehead—three times a day for five minutes. The instrument used was a "pulsator." The application gave almost immediate relief to the headache. I can throw no light on the phenomena, except that vibration tends to relieve deep-seated congestions.

LETTERS, NOTES, ETC.

THE TRUE COLOUR OF TISSUES.

DR. HORATIO MATTHEWS (London, W.1) writes: The difficulty of estimating the true colours of tissues—for example, retina, etc.—which can only be examined by artificial light can be overcome by wearing plano lenses appropriately tinted to convert the spectral quality of the light used to daylight values on the principle of the Sheringham reflector. But the nature of the light used—that is, electrical, gas, paraffin, etc.—should be specified in ordering the lens.

EARLY DIAGNOSIS OF PHIBSIS.

DR. T. A. G. HUDSON (Oldham) writes: One or two further observations on Dr. Rivers on "The drooping shoulder," JOURNAL, January 22nd, p. 120 may be of interest. Although Dr. Rivers mentions Krönig in reference to his particular article with regard to the relationship of the scapula to its fellow of the opposite side and to the spine, he has not mentioned the fact that what is probably the earliest sign of phthisis is a diminution in the area of resonance of the isthmus of Krönig, commonly at the right apex. The area of normal resonance is equal on both sides and extends from 2½ to 3 in., and any inequality in this area would point to that apex being affected even before any other signs manifest themselves. To elicit this information it is best to percuss from behind the patient, and to use a flesh pencil so as to compare accurately both sides.

HYPERIDROSIS.

DR. WILTON H. ROBINSON (Pittsburgh, U.S.A.) writes in answer to the request from "Beaten" (November 27th, 1920) for a remedy for hyperidrosis: There is a remedy that I first saw mentioned in one of the English journals some years ago

that has never failed in the cases in which I have used it. It was given at that time for bromidrosis, but seems to be equally effective in the first condition. It consists of equal parts of lead plaster and linseed oil. It is applied as a plaster under a bandage, and allowed to remain on about forty-eight hours.

PROPERTY IN A DEAD BODY.

EVERY now and then somebody is surprised to discover that a testator cannot dispose of his own body; he cannot, for instance, leave it for dissection. The bequest is void, as there is no property in a dead body. The executors have a right to the possession of the body, and their duty is to bury it. Nevertheless, the Anatomy Act, 1832, does something towards enabling a man's wishes to be carried out. If a person, either in writing during his life or in the presence of two witnesses during the illness from which he dies, desires that his body shall be anatomically examined, the person having lawful possession of the body must cause the examination to be made, unless the husband or wife or nearest known relative requires interment without such examination. After such examination the body must be interred and although interment must generally take place within six weeks of the time when the body was received for examination, this period may be extended by the Home Secretary. One legal writer suggests that the popular prejudice against dissection may be due to the fact that it has been associated by statute with felony and murder. In 1540 permission was given to the masters or governors of the mystery and commonality of Barbers and Surgeons of London "to take, annually, four persons put to death for felony, for anatomies, and to make incision of the same dead bodies, or otherwise to order the same, after their pleasure for their further insight and instruction, in sight, learning and experience, or faculty of surgery." In 1565 Queen Elizabeth granted to the College of Physicians the bodies of four felons executed in Middlesex "that the president, or other persons appointed by the College, might, observing all decent respect for human flesh, dissect the same." In 1663, the number of bodies so granted was increased to six by Charles II. In 1752 it was enacted that the bodies of murderers executed in London or Middlesex should be immediately sent to the hall of the Surgeons' Company, to be dissected and anatomized, and the attempt to rescue any such body was made a felony.

THE ANTIQUITY OF SYPHILIS.

ETIENNE (*La Chronique Méd.*, November 1st, 1920) supports by quotations from Suetonius the contention that syphilis occurred in Europe before the Christian era. The author has convinced himself that Augustus Octavianus Caesar (first Roman Emperor, born 63 B.C.) suffered from hereditary syphilis. The evidence advanced will scarcely appear convincing to the unbiassed critic; it consists in the early death of the father of Augustus Caesar, in the record that his mother suffered from a cutaneous lesion of serpentine form, and in the statement that Augustus himself, who had small, unequal, widely separated teeth, pigmentation of the skin, cutaneous eruptive lesions, weakness of the left hip, thigh, and leg, and paresis of the right index finger, suffered periodically from attacks of pulmonary congestion, followed by psychic disturbances. Augustus Caesar, it may be remarked, died at the age of 77 or thereabouts.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 32, 33, 36, 37, and 38 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 34 and 35.

THE following appointments of certifying factory surgeons are vacant: Horbury (York, West Riding), Penmachyn (Carmarvon), Portree (Inverness).

THE Dunlop 1921 Calendar, cleverly produced in oil facsimile by Raphael Tuck and Sons, Ltd., in conjunction with the Dunlop Company's Advertising Department, depicts a night scene in Piccadilly Circus. We understand that the accompanying date pad has been printed in almost every civilized language.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Order must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, not later than the first post on Tuesday morning, and, if not paid for at the time, should be accompanied by a remittance.

NOTE.—It is the rule of the Post Office to receive post-restante letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

166 Vaccine Treatment of Typhoid Fever.

LUNA (*La Pediatria*, August 1st, 1920) reports on 175 cases of typhoid fever in children treated by Di Cristina and Caronia's vaccines. The cases were classified in four groups—namely, 4 very severe, 52 severe, 74 moderate, and 25 mild. The intravenous, intramuscular, and subcutaneous routes were employed in various cases. With the subcutaneous route an average of five injections of 7.50 c.cm. of the vaccine was given, with the intramuscular route four injections of 5.15 c.cm., and with the intravenous route three injections of 1.10 c.cm. The reaction was, as a rule, much more marked after intravenous than after intramuscular injection, but recovery was more rapid. The action of the vaccine was slowest in subcutaneous injection. KHARVY-MARINUCCI (*Ibid.*, July 15th and August 1st, 1920) reports 80 cases of typhoid and paratyphoid fever in children treated by vaccines prepared according to Di Cristina and Caronia's method. Only three deaths occurred, due to pneumonia, intestinal haemorrhage, and toxæmia respectively. Apart from these three cases the vaccine had a beneficial action on all the patients. The number of injections which were given intramuscularly varied with each case. Sometimes a single injection was sufficient to produce complete defervescence, in others several injections were required. As a rule three to five injections given on alternate days were sufficient. Nine cases developed complications—namely, intestinal haemorrhage (3 cases), pyelocystitis (4 cases), broncho pneumonia (3 cases), pleuropneumonia (1 case), and various suppurative processes (8 cases). The vaccine did not appear to have any preventive or curative action on intestinal haemorrhage.

167 Influence of Trauma on the Distribution of Psoriasis.

SMALL (*Edin. Med. Journ.*, January, 1921) says that the influence of trauma on the distribution of psoriasis was seen in two distinct groups of cases in the army. (1) Those in which the disease first made its appearance in the neighbourhood of wounds. (A plate illustrating psoriasis around a gunshot wound on the back is shown, the man had had previous attacks of the disease.) (2) Those in which the psoriasis became superimposed on some other cutaneous malady—for example, impetigo, scabies, seborrhoea, etc. In this group the psoriasis adopts the distribution of its predecessor. (A plate shows psoriasis following scabies and impetigo, this man had no previous history of psoriasis.) Small combats the theory that psoriasis and seborrhoea are the same pathological entity by inference to these groups, affirming that psoriasis in a seborrhoeic subject will have its distribution influenced by the pre-existing seborrhoea. He concludes by suggesting that psoriasis is more a general than a local disease, and that its almost constant occurrence on the knees and elbows may be attributed to the greater degree of friction to which these parts are liable.

168 Mantoux's Intradermo Reaction in Infantile Tuberculosis.

SALVETTI (*La Pediatria*, October 15th, 1920), who had previously performed von Pirquet's reaction with human and bovine tuberculin on 600 children, now records the results obtained with Mantoux's intradermo reaction in 500 children, in the great majority of whom human tuberculin only was used. The dose of tuberculin injected was always 1 mg. The results almost entirely agreed with those of the cuti reaction. A positive reaction was obtained in 131 cases, or 26.20 per cent., and a negative reaction in 369, or 73.80 per cent. Salvetti regards a positive reaction in an infant as possessing a high diagnostic and prognostic value, as it indicates a recent infection which may progress, clear up or become inactive. A negative intradermo reaction which is normal in the infant diminishes in frequency with advance in age, and it is only in the older child that it possesses considerable diagnostic and prognostic value, for in such cases, especially if repeated, it excludes with relative certainty the possibility of tuberculosis. Salvetti concludes that Mantoux's reaction is the most suitable method for revealing tuberculous infection in infancy.

169. Irradiation of the Hypophysis in Bronchial Asthma.

A-COLI and FAGIOLI (*Rif. Med.*, July 20th, 1920) have obtained good results in the treatment of asthma by irradiation. They irradiate three different fields—one frontal and two temporal—at a focal distance of 45 cm., using an aluminium filter of 2 mm., S.E. 18–20 cm., ma 31. The treatment is conducted for twenty-five to thirty minutes at a time, at intervals of a week, about four sittings being necessary. In the five cases of which they give brief notes decided relief and almost complete cessation of the attacks of asthma was noticed. They have also had success from similar treatment in a case of dystrophia adiposus genitalis and one of scleroderma. On the other hand, no marked good was derived from irradiation in a case of infantilism, one of angioneurotic oedema, and three cases of diabetes mellitus. It is understood that if there is no pituitary gland left, irradiation treatment, given with the object of stimulating the endocrine glands, is not likely to be successful.

170 Serum Treatment of Meningococcal Septicæmia.

KJALLR (*Tidsskrift for Læger*, September 16th, 1920) urges the necessity for early treatment of meningococcal septicæmia by means of large doses of serum given intravenously. The clinical picture being characteristic, it is not always necessary to wait for a bacteriological confirmation of the diagnosis. He records two cases to show that even in desperate and practically hopeless cases early serotherapy may save the patient. Though this treatment was instituted in both cases on the strength of the clinical diagnosis only, a bacteriological examination was subsequently made and meningococci belonging to Type A were found in both the throat and the petechiae. In one case seven injections were given—five into a vein, two into a muscle—on seven successive days. The amounts were 30, 20, 20, 30, 30, 20, and 30 c.cm. respectively. In the second case only two intravenous injections of 30 c.cm. each were given. The author notes that Type A appears to be the most prevalent form of meningococcus in Denmark, constituting about 90 per cent. of all cases.

171 Septic Infections of the Urinary Passages in Children.

JEMMA (*Rif. Med.*, November 6th, 1920), in a clinical lecture on a case of coli bacilluria in a child of 2 years, points out that in a child suffering from irregular intermittent fever, pallor and intestinal disturbances, when other causes have been excluded, one ought to think of coli bacilluria and examine the urine. In the child in question typhoid, paratyphoid, Malta fever, relapsing adenoiditis, syphilis and tubercle were all excluded on clinical grounds, confirmed by negative reactions to the various serum tests, and on examining the urine pus and *B. coli* were found. Too many of these cases are attributed to gastric disturbances, examination of the urine being omitted. The urinary symptoms at this age may only be slight, especially if the kidney is more affected than the bladder. Whether the bacillus enters from without, or from within the blood or lymphatics, is uncertain. If there are no complications the prognosis is good, but sometimes bronchopneumonia or diarrhoea may complicate matters. Treatment by urotropin, helmitol, or salol, and the drinking of plenty of water, give satisfactory results. The urine is usually acid. The author does not mention the treatment by sodium bicarbonate and potassium nitrate. Washing out the bladder is seldom necessary.

172 Osteochondritis Deformans Juvenilis.

ACCORDING to MOUCHET (*Bull. et Mem. Soc. de Chir. de Paris*, December 14th, 1920), this condition, which is called by the Americans Legg's disease and by the Germans Perthes's disease, was previously described in the newborn by the French writers Menard and Soudat. It is a relatively rare affection, as Sorrel has observed only 6 cases among 1,500 children under his care at the Maritime Hospital at Dieppe for chronic osteo-articular lesions. Two thirds of the cases are in boys. The age ranges from 3 to 12 or 13 years, the most frequent age being 5 to 9 years. Unilateral involvement is the rule, the right side being affected as much as the left. As a general rule the limp is only slight, and the movements of the legs are not much restricted. Extension is normal, flexion and external or internal rotation are little if at all affected, but abduction

is constantly limited. X-ray examination, which is all-important in this disease, shows special changes in the head of the femur, the epiphyseal cartilage, and the neck of the femur. The epiphyseal nucleus in the head of the femur is often broken up into two or three nuclei: the epiphyseal cartilage is very irregular, and the neck of the femur shows clear areas below the epiphyseal cartilage. Treatment consists in immobilizing the limb by plaster or continuous extension.

173. Myasthenia Gravis with Osseous Changes.

LIBREBOULLET, IZARD, and MOUZON (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, December 30th, 1920) record the case of a woman, aged 33, who had suffered from myasthenia gravis for thirteen years, the diagnosis having been confirmed by Goldsman, who was the first to describe the disease. The remarkable features in her case were, first, the slow course of the disease, which allowed her to lead an active life for thirteen years; secondly, the occurrence of changes in the bones of the face; and, lastly, the association of obesity and amenorrhoea. The bony changes consisted of a deformity of the superior maxilla, giving rise to a deviation of the central and lateral incisors, which were projected almost directly forwards and upwards, with wide gaps between each. X-ray examination showed that the lesions were due to well marked decalcification.

SURGERY.

174. Thoracoplasty in the Treatment of Pulmonary Tuberculosis.

BULL (*Il Morgagni*, September 25th, 1920, and *Medical Science*, March, 1920) speaks favourably of excision of the ribs in phthisis. He has operated on 37 cases, divided into two groups of 24 and 13. In the first group there were three deaths and in the second only one. The improvement in the mortality of the second series is attributed by the author to the division of the operation into two stages. In the first stage the fifth to eleventh ribs are removed under local anaesthesia and the further stages of the operation are performed under general anaesthesia. The best results are obtained when 120 to 130 cm. of rib are removed. As a result of his experience Bull recommends removal of the first rib as a routine procedure. After the operation the muscles are sutured with catgut and the skin flaps with silk; a glass drainage tube is kept in for two or three days. Where the cavity remains rigid, fat taken from the abdomen may be used to induce collapse. In 5 out of 9 cases fat so removed constituted a fibro-lipoma around which the local tissues cicatrized regularly. Of the 33 patients who survived the operation 7 have since died of tuberculosis; of these one lived four years and another died of influenzal pneumonia. Of the 25 now living, 11 are cured, that is, have no fever, no bacilli, and no cough, and are able to carry on their regular occupation. The others still present symptoms of phthisis, but show some signs of improvement; it is less than a year since they were operated upon. Unfortunately one cannot guarantee that the lung on the unoperated side will remain free from tubercle.

Physiology of Wound Repair.

175. R. INGEBRIGTSEN (*Norsk Mag. for Laegevidenskaben*, December, 1920) has carried out investigations into the processes of repair of superficial wounds with a view to controlling the researches of Carrel and Lecomte du Noy. The author's findings, which concern seven series of investigations, are confirmatory and supplementary. Employing the imposing mathematical formulae worked out by du Noy, he found out that the rate of healing of a wound after it had become sterile conformed to the laws enunciated by du Noy as far as ordinary surgical treatment was concerned. But when he adopted treatment with compresses soaked in 0.3 per cent. silver nitrate and alternated this treatment with insolation, he found the rate of healing to be far more rapid than with Dakin's solution, which only sterilizes but does not stimulate the tissues. He is not prepared to state which is the more important, silver nitrate or sunlight, but he is so impressed by the value of the combination of the two that this treatment has been adopted at his hospital in every case of superficial injury.

176. Fibrous Osteitis and Inherited Syphilis. MOUCHET (*Bull. et Mém. Soc. de Chir. de Paris*, December 21st, 1920) has recently observed two cases of fibrous osteitis which were undoubtedly due to inherited syphilis.

One of the patients was a girl of 13 who had had pain in her right foot due to involvement of the astragalus since the age of 4 years. The pain had improved as the result of treatment, but the anatomical condition of the astragalus had not undergone any change. The other case was in a girl, aged 17, who had suffered for some months from pain in the right trochanter. There was slight atrophy of the right lower limb, but the gait and movements of the hip and knee were normal. There was slight tenderness on pressure over the trochanter without any increase in size. X-rays showed the rarefaction and polycystic appearance characteristic of fibrous osteitis. Subsequently the girl slipped on the floor and fractured her femur at the site of the fibrous osteitis.

177. Frequency of Extragenital Chancres.

DELINOTTE (*Rev. de l'ar., d'otol., et de rhinol.*, November 15th, 1920) devotes his Bordeaux thesis to a study of 192 cases of extragenital chancres which have occurred in various hospitals in Bordeaux during the last thirty years, as compared with 703 cases of genital chancres during the same period. Extragenital chancres are most frequent in men, in whom two-thirds of the cases occur, the favourite age being 20 years. Chancres of the lips are the most frequent, especially of the lower lip. Glass-blowing chancre, according to Delinotte, is less frequent than in former years. Next come chancre of the tonsil, of which a polypoid form has recently been described (*vide EPITOME*, April 24th, 1920, para. 444), and then, in decreasing order of frequency, chancre of the chin, which is usually due to the barber's razor, and chancre of the female breast, anus, and tongue, where the lesion is usually on the dorsum. Chancres of the limbs, ear, and nose are much rarer. Other very unusual situations for chancres, of which Delinotte records illustrative cases, are the gums, the male breast, and the ocular conjunctiva.

Reflex Calculous Anuria.

178. SALA (*Il Policlinico, Sez. Prat.*, November 1st, 1920) reports a fatal case of calculous anuria in a woman, aged 43, who was suddenly seized with a severe pain in the right flank followed by vomiting. A few days later a tender swelling developed in the right lumbo-iliac region. The amount of urine gradually diminished until complete anuria ensued. Gynaecological examination showed atresia of the vagina with infantilism of the external genitals. This condition suggested the possibility of the kidney being a single one as well as being ectopic. Cystoscopy, however, which might have confirmed this, was refused. Exploratory operation showed an ectopic right kidney in the lumbo-iliac position without any torsion of the pedicle or calculus in the renal pelvis. Death took place three days after the operation, and the autopsy showed absence of the uterus, ovaries, and left kidney. There was a small calculus in the right ureter, which did not, however, completely block the lumen, so that the renal secretion must have been diminished and then abolished by a unilateral reflex.

Diathermy an Aid in Empyema.

179. HIRSH (*Med. Record*, December 18th, 1920) quotes a case of long-continued empyema, with osteomyelitis in both fragments of each of the resected ribs, and a great variety of complications requiring a number of major operations, without any good result until diathermy was employed. So great was the improvement that a series of chronic cases with various complications were similarly treated with uniformly satisfactory results, especially in cases of haemolytic streptococcus origin, with or without osteomyelitis. Treatment was given daily to the affected region, one electrode being placed directly over the inflamed area, including the incision scars and discharging aperture, and the other over the antero-lateral surface of the chest, both being moved downwards in the course of treatment to take in the areas treated by Carrel's tubes. In the case quoted suppuration gradually ceased and all evidence of rib involvement disappeared, with complete correction of the deformity and improvement in the patient's general condition.

Chronic Pyogenic Osteomyelitis

180. DE GAETANO (*Rif. Med.*, August 21st, 1920) reports a case of chronic osteomyelitis (forty-three years' duration) of the thigh. The patient, who was 60 years old, was struck on the thigh at the age of 11, but there was no bone injury. The present illness began at 16 years, when the left thigh began to swell in a uniform manner, and after a time pus was discharged. This condition had persisted, but did not interfere much with his work. There was no

history of syphilis or tubercle, and the Wassermann and von Pirquet tests were negative; tubercle bacilli were found. Examination of the pus gave an almost pure culture of *Staphylococcus aureus*. Several sequestra were removed. The most striking feature of the case was the chronicity it began as a chronic affection without any general illness or any local injury, for the blow at 11 years was a temporary affection, and recovery appeared to follow in the course of a few days.

181 Treatment of Nasal Sinusitis.

ALIKHAN (*Reu. de l'otol., d'oto-l., et de rhinol.*, December 15th, 1920) uses the following method of treating retention of purulent secretion in the nasal fossae. The patient is told to empty part of the air in his lungs. His nostrils are then compressed, and he is made to inspire by the nostril without opening his mouth. Next the doctor counts up to six, and the patient is then allowed to open his mouth, the object of the buccal respiration being to prevent the air returning into the sinuses when the air is passing into the nostril. This method has yielded excellent results in acute sinusitis at the stage when surgery is not indicated and is specially useful in the differential diagnosis of sinusitis from purulent rhinitis.

182 Thrombosis of the Central Artery of the Retina following Ophthalmic Zoster

ALPAND (*Yvon med.*, December 10th, 1920) records the case of a woman, aged 75, who forty days after the appearance of ophthalmic zoster on the left side, suddenly lost the sight of her left eye without any preceding strain or injury. Ophthalmoscopic examination showed left optic atrophy and necrosis of the central artery without any retinal haemorrhages. The absence of any cardiac lesion enabled the diagnosis of retinal embolism to be excluded in favour of thrombosis due to endarteritis obliterans, the localization of which was due to the ophthalmic zoster.

OBSTETRICS AND GYNAECOLOGY.

183 Prognosis of Eclampsia

MARALDON (*Journal de med. du Bord aux.*, October 25th, 1920), in his Boderoux thesis, discusses the prognosis of eclampsia from the statistics of the Bordeaux Obstetrical Clinic from 1899 to 1919. The treatment, which consisted in bleeding under oscillemetric control, purgation and administration of chloral per rectum and by mouth, gave as good results as treatment by narcotics or by rapid and systematic emptying of the uterus, as is shown by the following figures: Among 54 cases occurring during pregnancy, the maternal mortality was 18.5 per cent and the foetal mortality 38.5 per cent; among 16 cases occurring during labour the maternal mortality was 6.2 per cent and the foetal mortality 18.7 per cent; among 12 cases occurring in the puerperium the maternal mortality was 8 per cent and the foetal mortality 25 per cent. Thus, among 82 cases the maternal mortality was 14.6 per cent and the foetal mortality 32.9 per cent.

184 Intestinal Obstruction and Tubal Pregnancy

HANAK (*Wien Klin. Woch.*, November 22nd, 1920) records a case of intestinal obstruction in a woman aged 31 associated with a pregnancy in the right Fallopian tube. The patient had been operated on for tubal pregnancy on the same side three and half years previously, and the intestinal obstruction was found to be due to adhesions between the small intestine and the adnexa on both sides. Complete recovery followed extirpation of the right tube and ovary. The occurrence of ectopic pregnancy on two occasions Hanak attributes to the presence of salpingo oophoritis, the origin of which could not be determined, as gonorrhoea was denied. Hanak has been unable to discover any previous examples of the association of intestinal obstruction and tubal pregnancy, and has found only five other cases of ectopic pregnancy occurring twice on the same side.

185 Ectopic Pregnancy and Rupture into the Caecum

CHASE (*Med. Record*, December 4th, 1920) describes the case of a patient, aged 25, in whom three months amenorrhoea was followed during six weeks by painless, haemorrhage, and subsequently by vomiting and hypogastric pain, which continued for seventeen days. At this juncture the pain diminished, but a large amount of dark, clotted and bright red blood was passed by the rectum. At the time of her admission to hospital, in a state of grave anaemia and collapse, examination was negative

except for a mass the size of a fist in the right side of the pelvis. At operation the caecum was found to be adherent to the posterior surface of a ruptured right tubal gestation, the caecum and the sac communicated by an aperture larger than half a crown, and the foetus, together with much blood clot, lay in the caecum. The rent in the caecum was repaired, the ectopic mass was removed, and a drain was placed in the posterior fornix. The patient recovered.

186 Rupture of Uterus at Caesarean Scar

KIRKMAN (*Pract. Med. and Surg. Journ.*, November 18th, 1920) records the case of a 3 para, aged 27, who had undergone two Caesarean sections, and in the thirtieth week of her third pregnancy suffered suddenly from cramp in the lower abdomen and from vomiting, not associated with severe pain. Half an hour afterwards the general condition was good, the pulse was 75, and the temperature normal. The foetus could be palpated with more than usual ease, but the palpability of the uterus was doubtful. Shortly after a discharge of bright red blood had occurred per vaginam laparotomy was undertaken. The peritoneal cavity contained fresh blood, and the dead foetus (still enclosed within intact membranes), as well as the placenta, lay free in the abdomen. Supravaginal hysterectomy was successfully performed. The T shaped rupture was situated in the anterior wall of the upper part of the uterus, and corresponded generally in position to one of the old scars.

187 Gland Tubules in the Fallopian Tubes

WATKINS (*U. S. Surg. Bull.*, October 16th, 1920), who has made observations on several species of mammals, shows that at certain periods tubular glands exist in the tubes near the isthmus. During gestation, for example, the mucous coils of the sac penetrate deeply into the wall, lengthening and hypertrophying like those in the uterine endometrium. This can be seen well in the gravid bitch. Towards the end of parturition the mucosa of the tube is so occupied with tubules that there is scarcely room for the collagenous connective tissue. After delivery the lining cells of such tubules undergo degeneration. In the human female the glands are much less numerous, but as in other mammals, they are quite apparent in pregnancy. The observation is of interest because it explains the occurrence of gland tubules found in the Fallopian tubes in certain inflammatory conditions and in some neoplasms.

188 Late Results of Conservative Operations for Myoma Uteri

SCHMID (*Centralblatt f. Gyn.*, October 30th, 1920) records the sequelae of 54 cases of conservative operation (enucleation or myomectomy) for myoma uteri. Recurrence was found in 9 patients; 6 of whom however did not present symptoms. Among 10 patients there had been fifteen subsequent pregnancies of which ten continued to term. Among 43 cases four patients reported increased menstrual loss (three for one approaching the climacteric), eleven had menstruation of unaltered character, and twenty eight (or 65 per cent) exhibited diminished duration and extent of menstruation.

189 Five-Year-Old Foetus Loose in the Abdominal Cavity.

SCHANNING (*Novi Acta Soc. Med. Natur.*, November, 1920) records the case of a married woman who consulted a doctor for varicose eczema of the legs. Quite incidentally she gave the following history. She had undergone a normal confinement at the age of 27. Since then she had never aborted. In December 1903, at the age of 44, she ceased to menstruate and soon exhibited definite signs of pregnancy. This was marked by several attacks of abdominal pain. After pregnancy had lasted about nine months labour pains set in and were followed by a slight haemorrhage, which lasted about a couple of days. After about twelve months amenorrhoea, normal menstruation returned returning regularly at four week intervals. On examination five years later the author found a large, nodular, freely movable tumour in the abdomen. Another tumour almost as large as an infant's head, could be felt in the right lower abdomen. Laparotomy was performed, and a foetus, weighing 1,250 grams, was found perfectly free in the peritoneal cavity. Filling the pouch of Douglas was a white, smooth tumour, adherent to the lower part of the gut. This tumour was also removed, together with a haemato-sarcoma on the right side. Uneventful recovery followed. The large tumour proved to be packed with brown soft material, consisting of organized blood or placental tissue. As the 7 to 8 cm. long cord, projecting from the ant. iliac, lay outside the membranes in which

the foetus was wrapped, the author suggests that they were not, as he thought at first, the original foetal membranes, but the result of a deposit of peritoneal fluid about the foetus after its escape from a ruptured tube. There was no free fluid in the peritoneal cavity.

190. Statistics of Fibroid Operations.

PESTALOZZA (*Il Policlinico*, Sez. Prat., November 22nd, 1920) gives the following statistics of 769 cases of fibroids on which he had operated during the last ten years. In 120 cases myomectomy alone was performed, and in these cases the superiority of surgical treatment over radiotherapy appeared to be indisputable. In 45 of these cases it was possible to cover the wound with the serous coat taken from the vesico-uterine fold, as in Pestalozza's method of pelvic hysteropexy. The total mortality was 2.4 per cent. In 16 cases fibroids were associated with cancer; in some instances there were ovarian tumours. Necrosis was present in 32 cases. Eight cases occurred in pregnancy; sixteen showed cavity formation; nineteen were of enormous size.

191. Treatment of Septic Abortion.

Or a series of 200 cases of septic abortion treated by HILLIS (*Surg., Gyn., and Obstet.*, December, 1920) half received no local treatment, and half were curetted; the former group had fewer days of fever, fewer complications, a shorter stay in hospital, and a lower mortality. It is concluded that cases of septic abortion should—excepting those in which haemorrhage threatens life—receive no local treatment until they have been for at least five days free from fever. On the other hand, it is advisable at the end of this period to curette cases which have become afebrile; this operation prevents subsequent bleeding and shortens the stay in hospital. Of 122 cases of non-septic abortion, no fewer than 32 per cent. were deliberately induced.

192. Pelvic Kidney Mistaken for Haematometra.

PETERSON (*Amer. Journ. of Obstet. and Gyn.*, November, 1920), in an article dealing with errors in gynaecological diagnosis, describes the case of a girl, aged 17, who had never menstruated, but had recently suffered from periodic attacks of malaise and lower abdominal discomfort. Rectal examination failed to reveal with distinctness either uterus or appendages, but a globular mass could be felt at the end of the examining finger. In the absence of a vagina this mass was taken to be a haematometra. At operation, after dissection upwards for three inches of the tissue between the rectum and bladder, a scalpel plunged into the mass called forth an alarming haemorrhage, which could only be stopped by a tight gauze pack. There was much subsequent haematuria. Peterson alludes to similar cases reported by Cullen and Engstrom, and to an instance in which a girl of 21 died from uraemia seven days after removal of a pelvic tumour which, in the absence of a vagina, had been originally diagnosed as a haematometra (Buss).

PATHOLOGY.

193. The Anaerobic Flora in Intestinal Diseases.

ACCORDING TO CAPONE (*Lo Sperimentale*, Fasc. i-iii, 1920), who has made a study of the anaerobic flora in certain morbid conditions of the intestine—namely, bacillary dysentery, enterocolitis of uncertain etiology, and typhoid fever—there is a great diminution and often a complete disappearance of the anaerobic putrefactive intestinal organisms in these conditions. He considers that some species of anaerobes which have been isolated exclusively from cases of intestinal disease cannot be regarded with certainty as the pathogenic agents of some of the diseases studied.

194. Xanthochromia.

LEVISION (*Arch. Int. Med.*, October 15th, 1920) reports three cases in which the spinal fluid obtained by lumbar puncture was of a bright yellow colour, and discusses the significance of this condition. Xanthochromia has been found in such a variety of spinal conditions that no etiological factor would seem to be common to all. It has been observed in neoplasms of the cord and its membranes, in the meninges, adhesions between the membranes, vertebral tumours and fractures, tuberculous meningitis and spondylitis, spinal gliosis with syringomyelia, multiple sclerosis, pachymeningitis, and several other conditions. The yellow fluid by itself is perhaps not of much importance, but when in association with the

colour there is an increased coagulability of the fluid, then there is practically always some obstructive lesion of the spinal canal. The obstruction to the flow of the cerebrospinal fluid allows of the formation of a pocket in which the fluid stagnates, and into which various elements pass by transudation from the vessels within its walls. It is sometimes possible to obtain haemoglobin reactions in certain cases of xanthochromia, and it has been suggested that there are minute haemorrhages into the spinal canal and ventricular spaces to account for the yellow coloration, and it may be that decomposition of the haemoglobin has proceeded so far in the other cases that one fails to discover traces of it. It must be admitted, however, that the occurrence of yellow spinal fluids is not yet satisfactorily explained.

195. Wildbolz's Auto-urine Reaction in Tuberculosis.

GRAMÉN (*Hygiea*, November 16th, 1920) has tested Wildbolz's reaction in about 50 cases of latent or active tuberculosis and in a certain number of healthy "controls." When the disease was definitely active the reaction was unmistakably positive, as shown by the formation of a small circumscribed swelling in the skin at the point where one to two drops of the patient's urine, reduced to one-tenth of its original volume by evaporation *in vacuo*, had been introduced by intracutaneous injection. In another class of case, in which the clinical signs pointed to more or less complete arrest of the disease, the reaction was either negative or faintly positive. Thus there would appear to be some justification for the claim, made by Wildbolz, that the auto-urine reaction distinguishes between active and latent disease, and is therefore superior to von Pirquet's tuberculin test, which only indicates presence or absence of infection without discriminating between infection and active disease. A disconcerting finding in some of Gramén's cases was a positive reaction, although the person concerned was either a "control" or a patient whose tuberculosis was, on the clinical evidence, arrested. But the author attaches such importance to the reaction that when it and the clinical evidence disagree, he is inclined to suspect the reliability of the latter. He experienced little difficulty in deciding whether a reaction was positive or negative, but he found at first some difficulties in the technique, for it was not easy to deposit the urine at the precise level of the skin where it would neither be too superficial and produce necrosis, nor too deep and thus fail of its object—hence the finding that of two simultaneous intracutaneous injections in the same person, one might be negative and the other positive. It is therefore advisable to give at least three injections simultaneously in different parts of the skin.

196. A Modification of Dargallo's Stain for Elastic Fibres.

DARGALLO (*Rev. Españ. de Med. y Cir.*, November, 1920) describes a modification of his stain for elastic fibres; the period of staining is thereby reduced from eight hours to fifteen to twenty minutes. A rather thick film of sputum is subjected to the action of nitric acid (1 in 3) for five minutes; without subsequent washing the stain is added, consisting in fuchsin (Ziehl) 3 parts, ordinary alcohol 2 parts, and saturated solution of ferric chloride 1 part. (The stain must be freshly prepared.) Washing is performed in running water, and may be supplemented, in the case of very thick films, by addition of ordinary alcohol or (momentarily) of nitric acid, 1 in 3.

197. Determination of Blood Volume.

HARRIS (*Brit. Journ. of Exp. Path.*, June, 1920), from an investigation of the vital red method of estimating the total volume of blood in the body, is of opinion that the values given are too high. In this method a known quantity of the dye is injected into the blood stream, and a definite amount of blood is withdrawn after a few minutes. By comparing serum dilutions of known strength before and afterwards the concentration of the dye in the sample can be determined. Harris states that the dye leaves the blood vessels even before it has spread uniformly through the circulating blood. The best interval for withdrawal of the test sample would seem to be from two to two and a half minutes after injection of the dye. The author, by using a control method which consists in the removal of the maximum amount of haemoglobin compatible with life whilst keeping the blood volume constant by the simultaneous injection of gum saline, suggests that a correction coefficient will give more accurate estimations in the case of the vital red values. This coefficient in man will lie between 0.8 and 0.9. Congo red, however, gives truer values, the correction coefficient in this case being 0.9 for four-minute samples.

PIONEERS AND EMPIRE BUILDERS: No. 110
FOURTH PERIOD, circa 8000 to 2500 B.C.

For Accuracy and
Convenience use

TRADE MARK 'SOLOID' BRAND
Antiseptics

Portable, compact and convenient.

Of precise strength and uniform activity.

Simply by adding the product to the necessary amount of water you get fresh, active antiseptic solutions of any desired strength.

No weighing necessary.

Example:

One 'Soloid' Corrosive Sublimate, gr. 8.75,
added to one pint of water = 1:1000 solution

'SOLOID' ANTISEPTICS include suitable strengths of all regularly-used agents.

Reduced facsimile

For full particulars, see Wellcome's
Medical Diary

EARLIEST DECORATIVE DESIGNS APPLIED TO NEOLITHIC WARE.—It was not long before the potter began to ornament the vessels he had discovered how to make. Lines were scratched in crude patterns upon the pots with sharp-pointed instruments, and an effective design was made with the finger-nails, as here seen in the upper three of the accompanying illustrations. An ornamentation was also made with a cord or string, which was pressed upon the clay before it was baked. One art often inspires another in a different material; the forms of early pottery vessels, as well as their decoration, recalls the basket-work, which was an earlier invention of the Neolithic people. The earliest fabricated receptacles were probably of basket-work, and when vessels began to be made of clay the accustomed forms, with their outward decorative appearance, seem to have been translated into the new material. On the right, two specimens of Neolithic basket-work are reproduced for comparison.

COPYRIGHT

Cows in New Zealand

Cows in New Zealand live in the open air and feed upon growing grass all the year round. Therefore, they are not apt to be affected by tuberculosis, and their milk contains a maximum of the growth-promoting factors or vitamins. That the potency of the vitamins is not impaired by the Glaxo Process has been conclusively proved by experimental demonstration and by years of clinical experience in all parts of the world, but more especially, of course, in Great Britain.

In New Zealand the danger of tuberculous milk is further guarded against by a strict system of Government control—supplemented, in the case of Glaxo, by our own independent inspectors.

Glaxo is, of course, an entirely British product, but its ever increasing success during the last twelve years as a builder of bonnie babies is, to no inconsiderable extent, due to its country of origin—New Zealand—where dairy science and hygiene have reached a standard unequalled anywhere else in the world.

A Clinical Lecture ON MUSCLE-TONUS, TONIC RIGIDITY, AND TONIC FITS.

BY
SIR JAMES PURVES STEWART, K.C.M.G., C.B.,
SENIOR PHYSICIAN TO THE WESTMINSTER HOSPITAL

ORDINARILY our voluntary muscles, even at rest, are in a state of slight tonus a sort of braced up condition. This muscle tonus is a reflex affair—that is, it is dependent, primarily, upon the integrity of the spinal reflex arc. The reflex arc, as we all know, consists of an afferent limb, made up of (1) the sensory nerve, leading up to the posterior spinal root, then (2) a short intermediate neurone within the grey matter of the spinal cord, and, lastly, (3) an efferent limb consisting, in series of the anterior cornual cell, the anterior nerve root, the motor nerve and the muscle.

Diminished Muscle Tonus—Hypotonia.

A lesion interrupting any part of this spinal reflex arc will cause among other phenomena, loss of muscle tonus. If the lesion be in the sensory or afferent limb—for example, in the posterior spinal root—it is often associated with sensory loss in the corresponding root area, if it is the efferent or motor limb which is interrupted, it is associated with muscular weakness and atrophy. A good example of loss of muscle tonus from lesion of the posterior roots is the muscular hypotonia of tabes, which is sometimes so extreme that the patient's limbs can be placed in all sorts of unusual postures. An illustration of loss of muscle tonus from a lesion of the motor part of the reflex arc is seen in paralysis of any motor nerve—for example, the posterior interosseous branch of the musculospiral, with its characteristic flaccid drop wrist.

Increased Muscle Tonus—Rigidity.

The opposite condition of excessive reflex activity with increased muscle tonus may arise from irritative conditions in the reflex arc. Sometimes the irritation is in the afferent limb of the arc as can be easily observed in the localized rigidity of the muscles around a painful or inflamed joint or the localized abdominal rigidity of an inflamed appendix. It may also result from irritative conditions of the anterior cornual cells—for example, in poisoning by strychnine or by the toxin of tetanus, although in tetanus as we shall see later, other factors are probably concerned.

Pyramidal and Extra Pyramidal Tracts Influencing Muscle Tonus.

All the movements of our voluntary muscles are executed through the anterior cornual cells of the spinal cord. These receive two different varieties of motor impulses from the brain. The first class of impulses are voluntary motor impulses, from the pre-Rolandic cortex, travelling down the brain stem along the pyramidal tracts. The second class are involuntary non-pyramidal impulses from subcortical motor centres (such as the corpus striatum, the red nuclei and the very vestibular nuclei of Deiters, etc.) travelling along subcortical spinal tracts (such as the

rubro spinal in the lateral columns, the vestibulo spinal in the anterior columns, etc.). The accompanying diagram, by Professor Stopford, of Manchester, shows what I mean. The subcortical ganglia are again influenced or reinforced by the intracerebellar nuclei (constituting cerebello-rubro spinal and cerebello vestibulo spinal paths, and so on). These two sets of impulses, cortical and subcortical, pyramidal and extra pyramidal, acting on the motor cells of the spinal cord, influence the motor activity of the anterior cornual cells, the pyramidal impulses producing voluntary movements, the non pyramidal impulses producing automatic acts. But, in addition, they have a regulating effect upon muscle tonus and posture which is mutually antagonistic, so that, if both sets of impulses be knocked out, the normal muscle tonus is diminished and the affected muscles become not only paralysed, but also flaccid. If, however, either the pyramidal impulses, on the one hand, or the subcortical impulses, on the other, are knocked out alone, the other partner is left

unopposed, and the affected muscles become hypertonic and rigid, producing so called spasticity.

The spasticity due to pure pyramidal disease—for example, in ordinary hemiplegia—is produced by the unopposed non pyramidal motor tracts. These act on the anterior cornual cells, and produce hypertonus in the affected muscles, which, although paralysed for voluntary movements, nevertheless can still be influenced by the subcortical centres in the corpus striatum, red nucleus, etc., so that certain automatic movements can be performed in the paralysed limb or limbs.

On the other hand, in the spasticity due to pure extra pyramidal disease (for example, in paralysis agitans, in progressive lenticular degeneration, etc.) automatic movements, such as those of swinging the arm in walking, blinking the eyelids, certain emotional movements of the face, etc., are diminished or lost, and yet the patient, owing to integrity of his pyramidal tracts,

can still perform all ordinary voluntary movements with his spastic muscles.

When both sets of motor impulses, pyramidal and non-pyramidal, are cut off, as in a total transverse lesion of the spinal cord (say from a fracture dislocation or from a bullet wound), the muscles below the level of the lesion at once become paralysed and we have a flaccid paraplegia—that is, one in which the paralysed muscles are devoid of muscle tonus. This flaccid stage lasts from one to three weeks. If, however, the spinal cord lesion is incomplete, so that some fibres, whether pyramidal or non pyramidal, still reach down to the anterior cornual cells below the level of the lesion, we then find that muscle tonus is preserved and increased from the start—that is, that the paraplegia is spastic in type. The transient loss of deep reflexes in a total transverse lesion compared with their exaggeration from the very start in an incomplete transverse lesion, is another point of interest, but we shall not discuss it on this particular occasion.

Decerebrate Rigidity.

Let us now consider what happens with a still higher transverse lesion of the brain stem, away above the spinal cord and medulla altogether, at a level which cuts off the cerebral hemispheres, together with their voluntary motor impulses, but leaves intact the great subcortical mechanisms of the red nuclei and vestibular nuclei, also leaving the ganglia free to be influenced by the undamaged cerebellum. When this is done experimentally

in animals, by transection through the brain-stem in the mesencephalon, the result is to produce so-called "decerebrate rigidity" in which the animal's limbs, both upper and lower, are rigidly extended, whilst the neck and whole spinal column, right down to the tail, are tonically hyperextended with retraction of the head. We note particularly that this lesion is a purely destructive or "negative" lesion.

In rare cases in human patients we may observe a fairly complete reproduction of acute decerebrate rigidity from unopposed activity of the subcortical motor centres. The following is an example:

In November, 1903, F. G., a man of 40, with albuminuria and arterio-sclerosis, had an attack of sudden right-sided hemiplegia of the face, arm and leg, with flaccidity of the paralysed limbs and unconsciousness. After an hour he recovered consciousness and was able to recognize his surroundings and to answer "Yes" and "No" to questions.

Three hours later he again suddenly became comatose with an entirely different group of symptoms. On top of the pre-existing flaccid right hemiplegia there appeared strong bilateral tonic spasm of the trunk, arms, and legs. The upper limbs were rigidly adducted at the shoulders, extended at the elbows, and hyperpronated at the forearms, so that the backs of the hands faced each other. The thumbs were turned inwards within the loosely flexed fingers. The lower limbs were rigidly extended at hips, knees and ankles, whilst there were occasional sharp sudden symmetrical dorsiflexion movements of both ankles. The spinal muscles were also rigid. The fingers and toes were flaccid. The upper limbs occasionally became flaccid for a few minutes, but the lower limbs remained rigid to the end. The pupils were small and inactive to light. The breathing was stertorous, with flapping of the right cheek. The knee-jerks were exaggerated and there was bilateral ankle clonus. The plantar reflexes could not be elicited owing to the frequent tonic spasms of the ankles.

The rigidity of the lower limbs and trunk persisted until death, which occurred four and a half hours from the onset of the original hemiplegic attack. The temperature ran up to 102° at the end. The pupils became widely dilated, the left being larger than the right; both were oval in outline, the left with its long axis horizontal, the right with long axis almost vertical. The pulse was 186 at the end.

At the autopsy the left lateral ventricle was distended with a large blood clot, and the left corpus striatum was ploughed up by haemorrhage. The other ventricles of the brain were normal.

Decerebrate rigidity in man is the result of a destructive lesion, usually a haemorrhage, in the mid-brain. This haemorrhage often spreads at the same time into the cerebral ventricles. It has been suggested that it is the intraventricular site of the haemorrhage which is the cause of the decerebrate rigidity, but I have repeatedly observed cases of extensive intraventricular haemorrhage in which there has been no rigidity whatever. It therefore seems to me probable that some other factor, such as oedema of the brain-stem, must be the decisive one in cutting off the cerebral pyramidal impulses and leaving the subcortical centres uncontrolled.

Acute decerebrate rigidity is usually a terminal phenomenon in a dying patient; but not always, as the following example will show:

Only last week I saw an old gentleman of 85 who had had two attacks of left-sided hemiplegia—the first at the age of 75, the second at 83—apparently due to cerebral thrombosis. Two months ago he had a couple of attacks of sudden unconsciousness and stertor, with half an hour's interval between them. In both of these he showed typical decerebrate rigidity, with tonic extension of the lower limbs at all joints, the upper limbs being tonically extended at the elbows and wrists, the intermetacarpophalangeal joints rigidly semi-flexed and the interphalangeal joints rigidly extended. The coma lasted forty minutes in the first attack and twenty minutes in the second. The pulse ran up to 120 during each attack. Throughout the attack he made clamping movements of the jaws. For a few minutes after recovering consciousness he was mentally confused, but soon became bright and alert again, with no evidence of aggravation of his previous slight hemiplegia. He then went two months without further attacks, and again had another couple, of similar character but milder in degree. From these again he has made an excellent recovery.

Incomplete Decerebrate Rigidity.

Short of complete decerebrate rigidity, we sometimes meet with phenomena of chronic incomplete decerebrate rigidity—for example, in cases of cerebral diplegia, and, to a less extent, in ordinary hemiplegia.

In a decerebrate animal with tonically extended limbs, if we turn its head passively to one side or to the other, there occurs, after a short interval, a curious exaggeration of extension in the upper limb towards which the animal's face is turned (so-called facial limb), together with a

diminution of the extension of the upper limb towards which its occiput is turned (occipital limb). Similarly, in certain cases of cerebral diplegia in which the subcortical centres are released from control, we can elicit so-called "conjugate automatic movements," so that, if the patient's head be turned, say, to the right, we observe that the left upper limb slowly becomes tonically flexed, whilst the right becomes extended. This phenomenon takes about a minute to reach its maximum. If we now turn the head passively to the opposite side, the attitude of the upper limbs becomes reversed.

Rigidity in Pyramidal Lesions.

Similar phenomena of decerebrate rigidity can sometimes be demonstrated in chronic hemiplegia, being limited, of course, to the hemiplegic limbs. Thus we may observe involuntary flexion of the hemiplegic upper limb when the face is turned away from the hemiplegic side, and involuntary extension of the hemiplegic limb when the face is turned towards the hemiplegic side.

Many healthy people make automatic extension movements of the upper limbs during the act of yawning (which of course is a subcortical phenomenon). By the ancients such movements were termed "pandiculation." These movements often remain well marked in the paralysed limbs in a case of severe chronic hemiplegia when the patient yawns or is tickled. The transient tonic extension which then occurs in the previously flexed rigid fingers, or the elevation of the paralysed arm, may delude the patient with the vain hope that he is beginning to recover voluntary power. But, unfortunately, these movements are not a hopeful sign. On the contrary, being due to uncontrolled activity of the subcortico-spinal motor tracts, the more profound the lesion of the pyramidal tract has been, the more marked is the pandiculation likely to be.

The well-known muscular rigidity with which we are all familiar as forming part of the classical syndrome of a pyramidal or upper motor neurone lesion, is easily recognised as due to uncontrolled activity of the subcortico-spinal motor tracts. In such a lesion the posture of the spastic upper limb in cerebral hemiplegia or monoplegia tends to be one of flexion of the elbow with pronation of the forearm and flexion of the wrist and fingers. The posture of the spastic lower limb is usually one of extension of the hip and knee, with plantar flexion and inversion of the ankle and slight dorsiflexion of the toes. These postures of the limbs occur in pure pyramidal lesions—for example, in ordinary hemiplegia of cerebral origin or in pure lateral sclerosis of the spinal cord with the "extended" type of paraplegia.

Rigidity in Extra-Pyramidal Lesions.

Muscular rigidity also occurs in pure extra-pyramidal disease from unopposed action of the pyramidal tracts. This is typically seen in paralysis agitans, in which rigidity of the face, trunk and limbs (generally beginning unilaterally) invariably accompanies the tremor and usually precedes it. In fact, severe rigidity may be present for months before tremor supervenes, or tremor may even remain absent, when we have the so-called "paralysis agitans sine agitatione."

On the other hand, if the pyramidal and the extra-pyramidal tracts are both affected together, as for example in a diffuse spinal cord lesion, we no longer find the decerebrate extended posture of the lower limbs; on the contrary, owing to loss of tonus in the paralysed extensor muscles, there is flexion of the hip and knee with dorsiflexion of the ankle, so that the limb as a whole is drawn up or shortened—the so called flexed type of paraplegia.

Cerebellum and Muscle-Tonus.

Let us now turn to the cerebellum and its influence upon muscle-tonus. The fundamental function of the cerebellum is that of muscular synergia or co-ordination. For the efficient performance of co-ordinated muscular act a certain degree of muscle tonus is necessary. The cerebellar cortex is mainly a receiving platform for afferent, cerebello-petal impulses, for example, those of equilibration from the semicircular canals, also the proprioceptive impulses from muscles and joints, impulses which normally do not rise to consciousness, although when they are disordered acute discomfort is at once felt. The motor

centres of the cerebellum are located mainly in the intra-cerebellar nuclei, including the dentate, roof, and emboliform nuclei. These nuclei exercise their influence upon the anterior cornua and the voluntary muscles, not directly, since there are no direct, efferent, cerebello-spinal paths leading down to the spinal cord. The action of the cerebellum on the brain-stem is an indirect one, thrown in, as it were, from a projecting branch. It is exercised mainly upon the red nuclei and upon the accessory vestibular nuclei of Deiters, from which, as we have seen (see figure), descending rubro-spinal and vestibulo-spinal tracts lead down into the main stem of the spinal cord to influence the activity of the anterior cornual cells. Each half of the cerebellum is connected with the contralateral red nucleus and with the ipsilateral nucleus of Deiters—that is, with the ipsilateral side of the spinal cord, since the rubro-spinal tract decussates before reaching the spinal cord, whilst the vestibulo-spinal tract runs down uncrossed in the ipsilateral side of the cord.

Destructive or Negative Cerebellar Lesions.

If the cerebellum be experimentally destroyed the tonus of the voluntary muscles is at once diminished. In unilateral cerebellar lesions this loss of tonus is confined to the ipsilateral limbs and trunk. The affection of the trunk muscles in unilateral lesions of the cerebellum is dramatically shown by the fact that the tonic action of the contralateral muscles being now unopposed, the animal rotates around its own long axis in a screw-like fashion. In a case of destruction of the right half of the cerebellum this rotation is in the direction of screwing in a screw; in left-sided lesions the direction is reversed (the animal's head representing the head of the screw).

Destruction of the anterior part of the middle lobe, or vermis, of the cerebellum affects the tonus of spinal muscles on both sides, so that in destruction of the front part of the vermis the animal falls forwards, whilst if the posterior part of the vermis be removed the animal falls backwards.

In human patients sudden destructive or negative lesions of the cerebellum are comparatively uncommon, but typical examples are occasionally met with in war. In unilateral wounds of the cerebellum the ataxia of the limbs is on the same side as the lesion. It is accompanied by hypotonia of the muscles on the affected side, so that the limb "flops about" and can be placed passively in abnormal postures. This hypotonia, however, tends to pass off after a week or two. In bilateral wounds of the cerebellum not only the limbs but the spinal and neck muscles become specially hypotonic, so that the patient cannot stand or even sit up unless he is supported. After a short time, if the lesion be stationary, compensation occurs, and the hypotonia rapidly subsides.

Irritative or Positive Cerebellar Lesions.

Lastly, we have to consider the effects of irritative or "positive" lesions of the cerebellum. These will increase muscular tonus and produce tonic rigidity of the affected parts. The mechanism through which this is effected is probably by means of intra-cerebellar nuclei, not the cerebellar cortex. Stimulation of the upper part of the dentate nucleus has been shown by Horsley and Clarke to produce deviation of the head and eyes towards the ipsilateral side. Stimulation of the basal portion of the dentate nucleus, together with the upper portion of the other adjacent intra-cerebellar nuclei on the same side, produces tonic flexion of the ipsilateral elbow, whilst stimulation of the parvocerebellar nuclei alone, without the dentate nucleus, produces tonic extension of both legs, closely resembling the posture of "decerebrate rigidity."

Tonic or Cerebellar Fits.

In rare cases we may come across rigidity in man from irritative cerebellar lesions, producing a variety of "tonic fits." In these so-called cerebellar fits the posture of the lower limbs in extension is what we have already described, but that of the upper limbs is not quite the same as in ordinary decerebrate rigidity from a negative or destructive lesion of the brain-stem above the red nuclei. In irritative cerebellar lesions the typical hyperpronation of the forearms is often absent.

Let me relate to you an example of these "cerebellar fits" which some of you have witnessed in the wards.

R. N., a little boy of 4 years, was healthy until the age of 3, when he began to have "fits." At first about two used to occur in every twenty-four hours, one during sleep and another on waking in the morning, but after a couple of months they rapidly increased in frequency, and by the time he came under observation they were occurring about every half-hour or so, day and night. Together with the increase in the fits, the child's intelligence rapidly deteriorated. Previously bright, active and lively, he became dull, apathetic, and neglectful of the sphincters; his speech, previously fluent, became less distinct, so that he intermingled inarticulate noises with his almost monosyllabic, indistinctly articulated words. He occasionally placed his right hand on the side of his head, as if in pain. There was no vomiting. A week before I first saw him he became unsteady in his gait and occasionally fell when walking.

When first examined, on May 1st, 1920, he was mentally dull, but he understood and executed verbal requests to shut his eyes, put out his tongue, etc. He named accurately objects shown to him, such as a watch, penny, and scissors, but articulated his words very indistinctly. The optic discs and fundi were normal. The pupils were equal and normal in reaction. There was a fine rotatory nystagmus, only noticeable during ophthalmoscopy. The cranial nerves were otherwise normal. There was no cutaneous anaesthesia or analgesia, and all the limbs were powerful. The gait was extremely unsteady and reeling, so that he frequently fell, but not constantly in any special direction. The knee-jerks were brisk and equal; the ankle-jerks were absent. The plantar reflexes were flexor in type, and the abdominal reflexes were brisk. Kernig's sign

of his fits, of which the

The child suddenly became anosis of the lips and face, of the eyes slightly to the of the eyelids. Meanwhile upper limbs became tonically

extended at the elbows and rigidly flexed at the wrists and metacarpo-phalangeal joints; the lower limbs were rigidly extended at the hips, knees and ankles. After lasting about twenty seconds, the lower limbs remaining rigidly extended as before. He then gave a deep sigh and recovered consciousness. There was no biting of the tongue nor affection of sphincters during the attack.

The patient was kept under observation in Westminster Hospital for two months, during which he had numerous daily attacks similar to the above, numbering from seven to twelve in the daytime and four to six at nights during sleep. At the onset of the fits the eyes were turned sometimes to the right side, sometimes to the left. After an attack the child was not stuporous but seemed wide-awake, and went on playing with his toys.

Radiograms of the skull showed no abnormality, and the optic discs remained normal. Bromide medication had no apparent effect on the frequency of the fits.

In view of the persistence of these cerebellar attacks I asked my colleague, Mr. Spencer, to do a decompressive operation. Accordingly, on July 25rd and 27th a two-stage operation was carried out, in which both cerebellar hemispheres were widely exposed, the straight sinus between them being divided and the dura freely opened. The cerebellum bulged markedly, especially its right hemisphere, but no tumour was seen or felt in any accessible part of the cerebellum. The wound was closed and healed uneventfully, but the flap remained bulging.

During the early half of August, following the operation, the fits continued for a time, but with much diminished frequency. In the latter half of August only four attacks occurred, and from August 30th onwards they ceased altogether.

When re-examined on October 26th, 1920, and again on January 4th, 1921, he was bright and intelligent, with normal speech and articulation. The optic discs and cranial nerves were normal. He was free from nystagmus. There was no weakness or ataxia of the limbs, and he walked and ran about like other children; but was said to be somewhat excitable and impetuous in temper. The operation flap bulged as before.

I may also remind you that many years ago Hughlings Jackson¹ regarded the phenomena of tetanic convulsions, with their tonic spasm of the face (risus sardonius), jaws, neck, trunk and limbs, as a variety of cerebellar fit. It is probable, however, that in tetanus the mid-brain nuclei and the anterior cornual cells are also implicated in the irritative process.

Another point of interest is raised by the head retraction and spinal rigidity of basal meningitis. Whether this is also to be regarded as a variety of cerebellar irritation is well worth consideration.

Time does not permit of our attempting any adequate discussion of other incomplete varieties of tonic fits. But those of you who are interested in the matter will find many suggestive points in a recent paper by Dr. Kinnier Wilson,² where the subject is discussed in greater detail.

DIATHERMY IN DISEASES OF THE
THROAT AND NOSE.*

BY

W. J. HARRISON, M.B., M.R.C.S.,

ASSISTANT SURGEON, THROAT AND EAR HOSPITAL, NEWCASTLE-ON-TYNE.

SURGICAL DIATHERMY—sometimes called the cold cautery—consists in coagulation of the tissues by heat generated in the tissues themselves by the passage of a high frequency current of considerable strength. Up till comparatively recently, high frequency currents were not used in surgery, only minute currents of a few milliamperes being used for the destruction of small naevi, removal of superfluous hairs, etc. In diathermy, currents running up to 1 to 2 amperes are often used in throat operations.

The first operations by this method in this country were performed by Professor Nagelschmidt of Berlin in Mr. Harmer's clinic at St. Bartholomew's in 1910. He removed a large malignant growth of the soft palate, an inoperable *vacrus* of the tongue, and enlarged tonsils. Mr. Harmer became the pioneer of this treatment in England, and since he showed his first case at the Laryngological Section of the Royal Society of Medicine (a case of inoperable cancer of the fauces) a great number of throat surgeons throughout the country have taken up this way of operating, and have recorded very satisfactory results. Although greatly interested after seeing Mr. Harmer operate on several cases, the war prevented my doing any cases till this year, and I have to thank the surgical staff of the Royal Victoria Infirmary, Newcastle-on-Tyne, for allowing me to operate on some of their cases.

In the following description of the method of using diathermy I have thought principally of operations for malignant disease of the mouth and throat; but in all essentials the method is the same for any growth. Various ends for the active electrode are used, and various methods may be used in dealing with the growth according to its size and situation (it may be removed or coagulated *in situ*), and different strengths of the current are needed; 300 to 400 milliamperes may be sufficient when an angioma has to be coagulated, and 2 amperes are required when dealing with a large malignant growth.

Prior to operations on the mouth and throat the mouth must be got into as healthy a condition as possible, and septic and decayed teeth attended to. At the time of operation the growth should be painted with iodine. A large negative electrode, thickly padded with cloths thoroughly wetted with saline, is placed on the chest, back, or thigh of the patient, and it is important to have this electrode lying evenly and in close contact at all points, otherwise burning may occur. I use three towels as the pad, and, if the operation is long, inspect the place to which they are applied, so that any signs of burning or scalding may be detected at once. The growth is dried and a small active electrode placed on it. The current is switched on and gradually increased until of sufficient strength, and it is then kept at this strength in the following applications. The result of passing a large current through this small electrode is that great heat is generated in the tissues below the electrode. They turn white and bubbles appear, and if the current is allowed to flow sparks begin to leap from the electrode. The application should not be long enough to allow these sparks to appear, and the current should always be switched off before the electrode is removed from the growth, as, if this is not done, sparks fly when it is taken off, and surrounding tissues are injured. The coagulation extends to a considerable depth, varying according to the strength of current and length of application. The whole growth is gone over in this way until it is coagulated *in situ*, and, should it be necessary to coagulate more deeply, some of the slough may be gently scraped away, and the electrode again applied. The tissues become intensely hot after one or two applications, and it is advisable to wait a short time to let them cool, or unnecessary damage may be done to surrounding parts.

As the heat coagulates the tissues it also sterilizes them, so that a large, deep, sterile slough remains. There is no bleeding during the operation, as blood vessels and lymphatics are sealed. This is a matter of considerable

importance, particularly in malignant growth, as these channels of septic absorption and dissemination of growth are left open in all cutting operations, and in cutting operations there is always a risk of implanting malignant cells in healthy tissues. Some of the slough may be gently scraped away to hasten its separation, but it should never be removed to such a depth that there is any risk of hæmorrhage, nor should any except quite loose pieces be removed, as it is being thrown off during the process of healing. There is often, after the operation, a considerable outpouring of lymph and oedema in the surrounding tissues. Cases have been recorded where tracheotomy has been required, and in all operations in the neighbourhood of the larynx this should be done as a preliminary.

The temperature may be raised for the first two days, but rarely reaches 100°, and generally subsides in forty-eight hours, when in many cases the patient may get up, even after extensive operations. There is soreness in the operation area, but the pain is less than in cutting operations or where a cautery has been used, and a patient whose soft palate and fauces I operated on was eating solid food on the third day. The resulting slough looks rather alarming, and makes one think of secondary hæmorrhage, septic absorption, and septic pneumonia. Secondary hæmorrhage is a danger when working near large vessels, but smaller vessels are closed by coagulation. Septic absorption is less than in cutting operations, for the reasons given above, and septic pneumonia does not occur more often than when the knife is used, and many say less often. I have had no cases up to the present. As the slough separates a healthy granulating surface is left, which rapidly becomes covered with epithelium, and in many cases there is little formation of fibrous tissue, so that a soft pliable scar results.

I wish to speak mainly of the use of this method in malignant disease, so I will only mention briefly some other conditions in which it has proved valuable.

Naevi and carcerous angiomas, situated on the lip, cheek, tongue, etc., have been dealt with very satisfactorily. They can be coagulated piecemeal when large and otherwise inoperable, and when they affect the lip or cheek they can be attacked from within the mouth so that no scarring results.

Tonsils.—In a certain number of cases the contraindications to removal are so strong that, although the tonsils need to be enucleated, they are not operated on, or only with much misgiving and hesitation. Such cases can be dealt with entirely satisfactorily.

Lupus.—Nasal lupus, as we all know, is one of the most intractable conditions. Scraping, cautery, ionization, x rays, local applications of drugs are all tried, often with little effect, and one works on with these cases for months. I have lately been treating by diathermy a few cases sent me by Dr. Bolam and Dr. Thompson. It is too early to make any definite statement as to cure in these cases, but Dr. Thompson, who has been watching them, agrees with me that they have made greater improvement in a shorter time than they would have done by other methods. (Nagelschmidt said he could do more in two or three applications than he had previously done with 600 to 700 hours' exposure to Röntgen rays.) All have been having x-ray treatment for some months. One patient, in whom both vestibules, the septum and the inferior turbinates were involved, has had four applications. The ulcerated surface is healed and, at present, no signs of growth can be seen. Another very similar case now shows only a small healing patch on the inside of the ala. The applications are very easy to carry out. A fortnight elapses between each treatment, which only takes a minute or two, and is practically painless, as cocaine is previously employed.

Nasal synechiae, nasopharyngeal filiform, and rodent ulcers have also done well under this treatment.

Turning to malignant growths of the mouth, fauces, etc., it is, of course, impossible in any case to make a definite prognosis. A small growth easily removed may rapidly recur, while in another case, where operation appears almost hopeless, the patient may remain free from recurrence, or it may only reappear after a long time, during which the patient has been in good health. One can only say that a slow growth, in which there is no involvement of the glands, occurring in an elderly person, offers the best prognosis; but even in such a case one at times finds a rapid recurrence, and the recurrence is often of a more malignant nature than the primary growth.

We may divide malignant growths into (a) those which can be operated on by the knife; (b) those which cannot be operated on by the knife. Many of the former cases can be safely and easily dealt with in the ordinary way, but in others operation entails severe shock and risk, both at the time of operation and subsequently. I do not wish to say that all cases should be operated on by diathermy,

* A paper read before the North of England Branch of the British Medical Association.

but many now operated on by cutting operations would be dealt with equally well, if not better, so far as the removal of the growth is concerned, and with much greater safety and comfort to the patient, were diathermy used. It is often very difficult indeed to cut sufficiently wide of a growth involving the floor of the mouth or the posterior half of the tongue, but comparatively easy to coagulate. Growths of the fauces, soft palate or pharynx involve severe operations which can be done with much greater ease, safety, and rapidly by diathermy. Growths in the aryteno-epiglottidean region must also be included. In many cases coagulation and cutting can be combined. I removed half a tongue in this way with no haemorrhage, and more widely than if knife and scissors alone had been employed. The lingual artery was tied to minimize the risk of secondary haemorrhage, but even then, had cutting alone been employed, there would have been free bleeding.

Passing to the cases which are inoperable by cutting operations, they may be divided into: (1) Those which can be operated on by diathermy; (2) those which are inoperable. Of the former group, some are attacked with the hope that recurrence will not take place for a long time, and others to relieve symptoms. Many growths are so situated that they rapidly pass beyond the range of the knife, and many patients are not seen till this stage is reached: growths of the tongue in its posterior part, fauces and pharynx are examples. Sprays, etc., are used to keep the growth clean, morphine to ease the pain; but the patient goes downhill steadily, suffering great pain and discomfort, and death is a relief to him and his friends. There are now numbers of such cases recorded who have been operated on by diathermy and have lived in comfort for a considerable time without recurrence; when recurrences have taken place, they have been treated again and life prolonged. I have such a case to show this afternoon. He had an inoperable growth of soft palate, uvula and left fauces in April, was treated by diathermy on May 6th, 1920, and there is no sign of recurrence at present. There are other cases in which life has not been prolonged to any extent, but where symptoms have been greatly relieved, and they have died a much less painful death. One of the things which everybody who has used diathermy has noticed is the great relief from, or modification of, pain that often occurs, even in cases in which the whole growth cannot be removed. Massive ulcerating growths causing dysphagia and dyspnoea may be treated, giving the patient relief from these conditions.

Diathermy is no more a cure for malignant disease than any other treatment, but it can be used not only in cases which are operable in the ordinary way with greater safety and often with greater advantage, but also in cases which are beyond the scope of the knife. Post-cricoid growths—86 per cent. of which occur in women, and many in comparatively young women—have been dealt with, and life prolonged and much relief afforded, the pain and difficulty in swallowing being greatly relieved and in many cases temporarily cured. The operation is by no means without risk, but the condition is so desperate that the risk is justified. Cutting operations show a very high mortality, and can only be attempted in very early cases. Stuart Low has shown a number of cases in which large masses of malignant glands, which could not be removed, have been delayed in growth and diminished in size, and pain greatly modified, by plunging a diathermy point into them in many places. He dissects the cutaneous tissues off the growth first, and after the operation sutures them again, and in no cases has he had any ill effects follow.

It has been impossible owing to time to mention much of interest, and only a brief outline has been attempted; but I shall conclude by tabulating the advantages and disadvantages of diathermy.

Advantages.

Shock is practically nil, even after extensive operations. Pain after the operation is less than after operation by knife or cautery.

Temperature is only slightly if at all raised, rarely reaches 100° and drops within forty-eight hours.

The dangers of metastasis are much less than with cutting operations, blood vessels and lymphatics being sealed.

Risk of septic absorption is less than in any other form of operation.

There is complete destruction of visible and palpable malignant disease, and probably many outlying cells are destroyed

which could not otherwise be reached. Malignant cells are of lower vitality than those of healthy tissue.

The operation is practically bloodless, is rapidly and easily performed, and can be easily repeated if necessary.

Tumours that are otherwise inoperable can be attacked.

Convalescence is rapid.

In many cases which are hopeless, relief can be given to the patient.

Disadvantages.

Healthy and diseased tissues are destroyed, but in cutting operations this also takes place.

Important vessels and nerves cannot be seen.

There is danger of secondary haemorrhage when working near large blood vessels.

There is a tendency to the formation of keloid when skin surfaces are involved.

THE MATERNITY HOSPITAL, WITH ITS ANTE-NATAL AND NEO-NATAL DEPARTMENTS.

BY

J. W. BALLANTYNE, M.D., F.R.C.P.Ed.,

PHYSICIAN IN CHARGE OF THE ANTE-NATAL DEPARTMENT OF THE EDINBURGH ROYAL MATERNITY HOSPITAL, ETC.

A NEO-NATAL ward and clinic, an ante-natal clinic, and a pre-maternity ward are all needed in order to complete a modern maternity hospital in its rounded fullness. Gynaecological and pathological departments may be added to the building or may be provided elsewhere, according to the requirements or the institutional resources of the city or town in which the maternity hospital is situated; but the neo-natal and ante natal departments are essential to the entire fulfilment of its purpose.

The maternity hospital occupies a separate place among hospitals, for, whilst they are designed for the relief of the sick, it is for the reception of many to whom the words "absolutely healthy" may be fitly applied. It is a hostel rather than a hospital. When Sir Thomas Browne wrote, "For the world, I count it not an Inn, but an Hospital, and a place, not to live, but to die in," he was not thinking of the ideal maternity hospital of to-day and to-morrow, but of the very real general hospital of his time. When criticism asks ironically if living healthy mothers accompanied by living healthy babies always emerge from maternity hospitals, one has, of course, to admit sadly that they do not. With this admission, however, one is now justified in asserting that the things of which they die are preventable in the case of the mothers, and generally so in the case of their infants. The recognition of the preventability of maternal deaths in connexion with parturition has become wonderfully clear in recent years, and systematized efforts are now being made in many places and by ante-natal clinics and pre-maternity wards really to prevent such fatalities. On account of a less degree of familiarity with the causes of the diseases of the newborn infant it is not realized how possible their prevention also is; indeed, it is scarcely recognized how terribly fatal these maladies are, although the separate publication of the neo-natal death rate does not long leave this depressing conclusion in doubt. Their severity and their preventability are the incentive and the justification for the neo-natal department of the maternity hospitals of the future.

The Maternity Hospital of the Nineteenth Century.

Up to the close of the nineteenth century the maternity hospital was held to have discharged its legitimate functions when it made itself responsible for the care of women in labour, and of them and their babies in the puerperium. Within this limited sphere of service they achieved a measure of success, and their occasional but rather spectacular failures were in process of restriction towards the end of the century by the introduction of the practice of antiseptic and aseptic principles. Their too complete concentration upon the act of delivery and upon the days of recovery following it was, however, a heavy handicap to real progress in the rational understanding and in the practical solution of the problem of attaining safety in human reproduction. No amount of perfection in operative technique or in instrumental resource could cancel or annul the absence of supervision and care in the ante-natal months; one might, if one cared, speak of the brilliant performance of a craniotomy, but the executive

splendour of such an achievement was certainly not that of the sun, and it hardly attained to the lesser degree of the moon, for one felt instinctively that when there were two lives at stake there was little glory gained by saving the one at the expense of the other. Further, in too many places the maternity hospital had come to be almost wholly the refuge of the illegitimately pregnant mother carrying her unwanted baby; ethical considerations were unwarrantably dragged into purely obstetrical problems; and as a result the "unco guid" left no large benefactions for such institutions, and their annual meetings were sparsely attended in contrast with those of the palatial infirmary and the much admired sick children's hospital.

The Maternity Hospital of the Early Part of the Twentieth Century.

With the dawn of the twentieth century came the development of the idea of the hospitalization of pregnant women and the concomitant conception of the prevention of obstetric disasters thereby. The "ambulant patients" of the past were more generously recognized as the "expectant mothers" of the present day, and the kindlier breezes of the spring-time began to play around the maternity hospitals and their inmates in place of the coldness of the winter's blasts. By and by, and, as it would seem, by a special providence, maternity as an outlier or sort of Cinderella sister of child welfare came with a rush into the full sunshine of national recognition, approbation, and encouragement, and this has been accompanied by a small trickle of pecuniary support, perhaps the herald of the refreshing and much-needed shower. In the bringing about of this welcome change many forces were doubtless at work. The falling birth rate played its part; the havoc of the war was the voice of the prompter; the great principle of modern medicine—that "prevention is better than cure"—was the prevailing motif; interest in the wonders of pregnancy as a symbiosis and in embryology as the fairyland of science took its place in the scenario; and the uprush of public opinion on the rights of womanhood to a full fruition supplied the insistent chorus. These all were there; but the concrete fact so far as the maternity hospital was concerned was the opening of pre-maternity wards and the starting of ante-natal clinics.

The Ante-natal Department.

The development of an ante-natal department began in different ways in different places. In the Edinburgh hospital, which the writer believes to have led the van in this forward movement, the beginning was the founding of a bed for the diseases of pregnancy in 1901. The bed was soon increased to a ward with four beds, and the name "pre-maternity," which the writer had given to the former, was soon extended to the latter. Other events followed. Pregnant patients at all ages of gestation began to be cordially welcomed at the hospital and urged to return for supervision; nurses with special knowledge of pregnancy and its maladies began to go amongst the expectant mothers, and persuade them to come to the hospital for advice regarding the inconveniences as well as the danger signals of pregnancy; such "pre-natal nurses" were furnished with schedules by the writer setting forth the chief danger signals and were encouraged to fill them up; then separate hours and days were set apart for the seeing and advising of pregnant women, and these came to be called mother-consultations or ante-natal clinics. Next, the system within the hospital was conjoined with the town scheme of maternity and child welfare, the hospital itself formed the head centre of the mother-welfare part of the scheme, and health visitors began to act as an auxiliary staff outside the hospital; then the scattered activities in the hospital were gathered together in an annexe of the building and called the ante-natal department; and, lately, the care of the expectant mothers suffering from the venereal diseases has been added to the other duties of this new department. In the building up of this elaborate edifice smaller stones had to be hewn and fitted in, but the portions mentioned above were outstanding, and the pre-maternity ward was the great corner stone. In a series of some thirty articles published at various times in various places the writer has described the stages of the progress of the idea and the details.

The hospitals in the large towns in England, in contrast to Edinburgh, seem to have started their ante-natal departments with the ante-natal clinic as a foundation,

and thereon to have built up towards the pre-maternity ward; but all do not seem to have reached that culminating institution. In the case of towns without a maternity hospital the ante-natal clinic allowed a beginning to be made to which a maternity hospital could be added later; but it can never be too often insisted that the ante-natal system without a pre-maternity ward or beds is dangerously incomplete, for whilst it ensures the detection of dangerous maladies in pregnancy it gives no destined place for their treatment. For pure prevention it may suffice (and that is much), but for curative success it is insufficient. In Glasgow, as may be learnt from the recently published report by Dr. Chalmers, the medical officer of health, ante-natal dispensaries and an ante-natal ward in the Glasgow Royal Maternity Hospital were opened between 1916 and 1918. In America the "pre-natal nurses" of Boston seem to have led the way in the development of ante-natal work, which later was affiliated with maternity hospitals and medical institutions; throughout it has been pre-eminently a movement in the full gaze of the public. During the war America to a large extent carried her ideas on mother and child welfare into France.

There have been differences also in nomenclature. Ante-natal clinics have also borne the names of pregnancy clinics, ante-partum consultations, free consultations for expectant mothers, and the like. The pre-maternity ward has been called the ante-natal or the pregnancy ward. One may speak of an ante-natal department or of a pre-maternity system; and of course the words ante-natal and pre-natal are synonymous. The writer's predilection is for pre-maternity ward and ante-natal clinic, but he has no strong preference. In 1891 or thereabout he was looking for a word which should express and include all the scattered subjects known as teratology, fetal diseases, germinal infections, monstrosities, morbid heredity, and the like, and he decided upon ante-natal pathology; but he was not strongly set upon it, and a mere turn of the die might have led him to pre-natal pathology, with the advantage of a syllable less to pronounce every time. Towards pre-maternity he had a much more decided leaning, and thought it more expressive.

It is hardly necessary in these days to write of the advantages to the maternity hospital of its ante-natal department. During recent months medical journals, and especially those devoted to maternity and child welfare, have published many appreciations; they have sometimes, too, added statistics, although the profitable time for discussing results has not yet come. The present danger, perhaps, is undue optimism, for there are parts of the subject which are still unknown, and the interrelations between mother and child are subtly complex. On the other hand, a maternity hospital which has added to itself an ante-natal department will not easily let it (with its illuminating "reports in advance") go again. It would be easy to enumerate some of the most obvious advantages it gives, such as an exact knowledge beforehand of the relation of the head of the fetus to the brim of the mother's pelvis, the correction of malpresentations and the rectification of malpositions, the prevention or cure of many of the smaller annoyances of pregnancy such as the pressure effects, the fully-informed treatment of many of the really severe danger signals of gestation such as those of toxæmia, the more accurate foretelling of the date of delivery, the estimation of fetal health or disease, and particularly the opportunity it gives for systematic treatment of the venereal diseases; but here it must suffice to emphasize more generally its outstanding value. That, in a word, is *prevention*.

The ante-natal department of a maternity hospital is like the air service of an army. Only a very incompetent commander would dare to attack without scouting, without a reconnaissance, and without his aviators who carry out both. Ante-natal supervision from the early months gives a bird's-eye view of the whole field of operations, and prepares the obstetrician for the attack he has to make upon the foe, that "old enemy" death and disease, at the time of the confinement. He may find no signs of enemy presence; so much the better for his patient and so much the easier for him. On the other hand, he may discover the carefully camouflaged battery or the deadly cross-roads, with the most immediately happy results in the adoption of an advance in another

and a safer direction. Without such foresight and foreknowledge he is blinded like the general whose aeroplanes cannot rise or have been sent down crashing by the enemy. In both cases fog is a trouble. In obstetrics it often takes the form of hydramnios or of some other abnormal intrauterine condition which hides the underlying facts. Further, the two services are alike in the risk which they run when communication is interfered with; when by reason of a fault in the "wireless" the aviators are not getting their messages through there is danger; so when, through a lack of hearty co-operation between the ante-natal department and the delivery part of the maternity hospital, the labour ward is not getting its reports, there is grave risk. The ante-natal clinicians are the air force of obstetrics, and indispensable.

The Maternity Hospital of the Near Future.

It may be safely predicted that when the maternity hospital has its ante-natal department in thorough working order—that is to say, when patients begin to come at early dates in their expectancy and when all that can be discovered about them is learnt with accuracy at each visit—there will follow an immense gain to the practice of the institution in certainty of diagnosis, in early prevision of danger and consequent rational choice of treatment, and in lessening of maternal, of fetal, and of infantile mortality and morbidity. Only of one disadvantage has the writer heard—the ante-natal department may spoil the operative work of the place! It may, of course, replace a craniotomy by a Caesarean section now and again, not altogether a disadvantage, one thinks; it may actually diminish the number of operative interferences, not without bringing some sort of relief to the expectant mothers.

Even the best of ante-natal departments, however, do not entirely solve the maternity hospital's difficulties. The infants have to be cared for after birth as well as before it. To some extent—nay, to a large extent—ante-natal care, by lessening the risks of premature labours and in other ways, makes it more likely that babies will be born alive and will go on living; but it is insufficient in itself to do all that is needed by the delicate infants, by those who are diseased or deformed, and by those who add prematurity to the other impediments in their way to life and health. For them there must be something more; that something more may be called the neo-natal department.

The Neo-natal Department.

It is quite unnecessary to argue on behalf of the need for some means other than what is now in our possession for the care of the neonate during the month which follows birth. It is sufficient to state again the well known fact that more lives are lost in the first month of the life after birth than in any other. The neo-natal death rate, which is for one month, is about 40 per 1,000 live births, whilst the infantile death rate, which is for twelve months, is about 100 per 1,000 live births. If the stillbirths are added to the neo-natal death rate, as they may very properly be, the result may be as much as 80 per 1,000 births. The present neo-natal death rate is a powerful and a sufficient argument for the provision of a neo-natal department, or at any rate of greater neo-natal supervision and care. What is needed is realization that many of the neo-natal deaths are preventable, along with the concentration of medical and especially of obstetric attention upon them.

The causes of the high neo-natal rate are not difficult to find. Some neo-natal disasters are, so to say, postponed deaths. But for the favourable circumstances of ante-natal life the unborn infant would have died before its expulsion from the womb, for it had the potentialities of death in it. Instances of this are found in grave malformations and marked tissue changes due to disease. Other disasters are due to an actual absence of knowledge regarding the causation of many of the peculiarly neo-natal maladies, regarding their diagnosis, and regarding an effective treatment of them. Instances are supplied by nearly all the diseases (such as icterus, haemoglobinuria, melaena, sclerema, and oedema) which appear with the word *neonatorum* after them. Yet others are due to the prematurity of the infant, and another group contains cases in which the fatal issue is the result of the traumatism of birth or of infections received during it. But there is yet another maleficent influence at work: neo-natal life lies, so to say, on the "divide" between two great departments of medi-

cine, between obstetrics on the one hand and pediatrics on the other, and it runs the risk of receiving insufficient attention from both. It is situated where obstetrics and pediatrics meet; and, so far as hospitals are concerned, its home is the interspace between the maternity and the sick children's hospital. In general practice the medical practitioner and the midwife are supposed to be in charge of the neonate as well as of his mother for a month; but it has to be admitted that too often the vigilance of both attendants flags long before the dangerous four weeks are over. It is to the honour of the doctor and the monthly nurse that brilliant triumphs have been recorded in the saving of weakly premature infants; but they are none of them achieved easily and they are sadly too few. A scrutiny of the complete returns of any maternity hospital (including the follow-up statistics of the babies who leave the institution about the twelfth or thirteenth day of life) will convince any who may be sceptical about the number of deaths which may be easily prevented at this age.

An attack upon the neo-natal mortality may, of course, be made by other means than the establishment of a neo-natal department in maternity hospitals. It may be made by banding the infants over to a sick children's hospital the moment they are born; but there are obvious disadvantages in this way of dealing with them, including their removal to a distance from their mothers and away from the attendants who have knowledge of the characters of the labour and the records of the ante-natal conditions. It may be done by the erection of special hospitals which may be named infants' hospitals or babies' institutes or "prematurities," and which would be under the care of doctors and nurses who would be, so to say, specialists in the management of delicate neonates; in these institutes also there might be well equipped laboratories for the investigation of the various problems of the causes of neo-natal deaths and for the preparation of the necessarily modified food. The great objection to such institutions is that it is unwise to increase the number of hospitals, especially in these days of financial strain, if their function can be performed by additions to existing hospitals. A neo-natal department in a maternity hospital may in the meantime meet the want.

The neo-natal, like the ante-natal, department must be a part of the maternity hospital; preferably it ought to be an annexe. It should consist of two parts—a pathological and a clinical. The former, which might be called the neo-natal pathological laboratory, should be devoted to research into the causes of early neo-natal deaths and of stillbirths, and would be under the care of an expert in ante-natal and neo-natal pathology. Already some hospitals have such a laboratory. In Edinburgh and Glasgow, for instance, for more than a year now the stillbirths and early neo-natal deaths have all been examined in searching necroscopies by Dr. F. J. Browne and Dr. A. M. Kennedy respectively, the latter working in a portion of the hospital, and the former in the neighbouring *post-mortem* department of the Edinburgh Royal Infirmary. The publication of these researches—which are being carried out under the Medical Research Council's Child Life Investigation Committee—ought to do much to advance the knowledge of neo-natal pathology. The clinical part of the neo-natal department should consist of a ward (or wards), not far removed but distinct from the ordinary puerperal patients' ward. The neo-natal ward will be furnished with electrical incubators and all other life-preserving means, will be under the management of physicians and sisters skilled in the treatment and nursing of newborn infants, and especially of premature and weakly ones, and will be most carefully guarded against infection. In some respects—for instance, in its temperature—its hygiene will be peculiar to itself, for it is really intended to serve as the real nursery, almost as the hothouse of the hospital. It must never be forgotten that a prematurely born infant is really a fetus struggling against the rigours of an environment for which he is not yet prepared; he is truly the tender exotic plant requiring the moist warmth of the conservatory until such time as his acclimatization is complete. There will be means for frequent weighing of the infants and apparatus for preparing milk according to chemical formulae carefully adapted to each child's requirements. In a word, there will be concentrated into this part of the maternity hospital all the devices of science and all the care of the obstetrical and nursing staff for that campaign

of neo-natal life saving which has here its special terrain. There will, of course, be special difficulties, such as the maintenance of touch between the babies and their mothers, but these are all capable of being overcome. When well enough the mothers will be welcomed in the ward and taught the nursing of delicate babies. The inmates will be all the babies born in the hospital or brought in from outside who call for special care because of injuries in labour, of delicacy of constitution, of the presence of disease, or, and most particularly, of prematurity of birth. A special place and differentiated handling will be afforded for the syphilitic babies and for those suffering from ophthalmia neonatorum. The age of the babies dealt with in the neo-natal ward will correspond with the name of the department; but here it is necessary to add a word of explanation. The ordinary neonate remains such for, roughly, a month after birth; but the fetus born at the seventh month of ante-natal life does not conclude his neo-natal existence till three months after his birth. If this obvious fact had been more generally recognized and acted upon there would not now have been so many neo-natal deaths recorded; such deaths were really ante-natal and not neo-natal in time, although they fell accidentally after the act of birth.

New Responsibilities.

The addition of ante-natal departments to maternity hospitals and their reinforcement with neo-natal departments has had and will have the effect of increasing the responsibilities of these institutions as well as of widening the range of their usefulness; but it will do more. It will increase—indeed it already has—the responsibilities of the hospital as a teaching centre. Both for medical students and nurses in training as midwives it is necessary to supply clinical instruction in the ante-natal and neo-natal departments. It is more than time that the exclusive or at least preponderating attention paid to teaching on the parturient and puerperal patient tacitly enjoined by the present regulations of the General Medical Council be extended and that tuition in ante-natal clinics and in the ante-natal and neo-natal wards be at least recommended in addition to the more usual and compulsory part of the training. It is, of course, essential that future practitioners should know about the handling of labours and the management of the puerperium, but it is most desirable that they shall be made familiar also with the examination of pregnant patients at all stages and with the hygiene and maladies of newborn, and especially of prematurely born, infants. Further, these additions will give a scope and a status to clinical obstetrics such as it does not now enjoy. It will then be a more complete presentation of the subject and will be less meagre in its content in comparison with clinical medicine and clinical surgery than it is at present.

The teaching of theoretical obstetrics will in turn be similarly affected. The lecturer will be led to give and pay more time and attention to ante-natal diagnosis and pathology and to neo-natal hygiene and disease than he commonly does now; and, again, as with the clinical aspects of the subject, a greater fullness will be introduced. The term "midwifery" is more truly descriptive of the teaching given to women in training for the examinations of the Central Midwives Board; something which both in nature and in extent surpasses this is what should be offered to the medical men and women of the future. The lectureship or chair might have been given the eminently and correctly descriptive name of genetics, but that term has been appropriated. Apparently we must fall back upon the term obstetrics, using that word in its widest sense.

The bearing on gynaecology of these ante-natal and neo-natal additions to the equipment of a maternity hospital is not necessarily direct. In Edinburgh the gynaecological department is in the Royal Infirmary, but in many places it is conjoined with the practice of the maternity hospital. In some respects this is admirable, for one large part of a gynaecologist's work is devoted to the repair of injuries and their results which are directly or indirectly due to faulty midwifery, and there is a distinct advantage in their being carried out in the same building. Thus the gynaecological department of a maternity hospital would serve the same purpose for the wounded puerperal woman which the neo-natal department discharges for the delicate infant. But it must not be forgotten that another large

part of gynaecology is concerned with the treatment of morbid states, such as malignant and myomatous tumours of the uterus, cystomata of the ovaries, and malformations which have no obvious or common connexion with child bearing. These are best dealt with in a surgical hospital for they are really nowadays a part of surgery. It looks almost as if gynaecology were on the point of breaking up into two parts—one containing conditions due to or militating against childbirth, and the other dealing with diseases and tumours common to surgery and gynaecology and special only in respect of the sex of the individual suffering from them. For the management of the first subdivision of gynaecological cases a department in the maternity hospital would be perfectly suitable; for that of the second subdivision the gynaecological ward of the general hospital would seem to be appropriate. The progress of the art and practice of obstetrics, as reinforced and aided by the work of the ante-natal department will be in the direction of limiting more and more the occurrences calling for reparative gynaecological operations, and happily, in time, of abolishing them altogether.

THE TREATMENT OF UTERINE HAEMORRHAGE NOT ASSOCIATED WITH PREGNANCY.

BY

JAMES PHILLIPS, F.R.C.S. EDIN.,

HONORARY SURGEON, BRADFORD ROYAL INFIRMARY.

In normal menstruation, when the superficial layers of the endometrium are cast off and blood is extruded from the abraded surface, clotting takes place very rapidly with abundant fibrin formation. Whitehouse* says: "The high thrombo-kinetic [blood-clotting] power of the endometrium is a provision of nature to facilitate clotting and prevent excessive haemorrhage. Even in well-marked cases of haemophilia profuse haemorrhage very rarely occurs during menstruation . . . Clinically . . . it is well known how rapidly, during the operation of curetting, the blood clots when mixed with the curetted endometrium, and special precautions are necessary to obtain tissue for microscopical purposes unmixed with clot." If, however, normal menstrual blood is examined after it has reached the vagina, it will be found to be almost completely fluid. Blood collected from the uterine cavity in a test tube is found to clot rapidly, but after some hours it becomes liquefied again. In other words, there is not only a blood-clotting substance present, but also a clot-dissolving substance, which normally produces liquefaction of the blood in the vagina, and so facilitates the evacuation of the menstrual discharges. There is evidence which suggests that the stroma cells of the endometrium secrete the clotting substance and the uterine glands the liquefying substance.

That ovarian secretion also exercises a profound control over menstruation is certain, and most probably the hormones of other endocrine glands are also potent, but little is known of how these act. Mechanical factors no doubt come in—for example, uterine muscular contractions may reduce menstrual loss by limiting the supply of blood to the endometrium. But the broad fact remains that the amount of menstrual bleeding is determined by the balanced action of various internal secretions about the mechanism of which we are at present without the knowledge which would enable us to control or regulate it. In practice we find that excessive menstrual loss usually occurs about the age of puberty or when the menopause is approaching. Excessive uterine haemorrhage during the child-bearing period is almost always associated with organic disease of the uterus or with some blood disease. The most frequent cause is, of course, fibroid tumours, and when a fibroid is accompanied by severe bleeding it will almost always be discovered either to be involving the endometrium, and thus likely to modify its secretory action, or it has itself undergone some degenerative change—necrobiosis, mucoid degeneration, red degeneration or malignant transformation—with consequent considerable chemical changes.

Until our knowledge has so improved that we are able to control the delicate balance of internal secretions, on

* Read at a meeting of the Bradford Medico-Chirurgical Society.

the upset of which appears to depend for the most part excessive uterine haemorrhage, in my opinion it is desirable to perform hysterectomy in all such cases whenever the bleeding is severe enough to make the patient to any extent an invalid. I am old enough to remember the time when it was considered so dangerous to remove a uterine fibroid that gynaecologists more often than not suggested not operation but rest and drugs when a woman anywhere near the menopause had a fibroid which did not actually threaten her life by reason of the profuseness of the bleeding. One of my most vivid memories is of a Sunday in 1896 when, on coming away from a visit to a lady of some 50 years of age, who had spent perhaps a dozen years constantly lying down either in bed or on a couch in an adjoining room, I was told that she had been all these years awaiting the cessation of a metrorrhagia due to a fibroid. I had watched Greig Smith remove large myomatous uteri safely and easily, and had seen more than one blanched feeble creature return a few months later to thank the surgeon for renewed vigorous health; and the contrast of a highly educated woman, whose keenly enjoyed activities had been brought to an end at the age of 40, was my first big stimulus to do surgical work—not just to save a patient from impending death, but from the far more ghastly death-in-life which constitutes existence for so many chronic invalids.

Briefly, in turn, bleeding (1) at puberty, (2) during the child-bearing years, and (3) about the period of menopause must be considered. Bleeding at puberty (1) may be severe, but practically always it rights itself, and I never even heard of any case which required hysterectomy. As I have indicated, it is probably due to imperfect balance between the various internal secretions.

Excessive bleeding during the child-bearing years (2) is, as stated before, most commonly due to fibroids, and, in my opinion, hysterectomy is indicated in almost every case where excessive bleeding, either menstrual or intermenstrual, is associated with the presence of a fibroid. Apart altogether from the bleeding or other urgent symptoms, there can be no doubt that fibroids interfere with good health. The association of myocardial degeneration and aortic disease with large fibroids is too frequent to be merely coincidence, and if a fibroid which has been found in the course of an abdominal section for some other condition is removed, the patient is almost certain to remark on her subsequently improved feeling of well-being.

Excessive bleeding may be associated with hypertrophy of the ovaries.

A year ago I operated on a patient of Dr. Lankester at the Bradford Royal Infirmary. She was a young woman, aged 26 years, who had had six children, and since her last confinement had had too frequent and profuse haemorrhage. When she was admitted she was obviously blanched, and had a soft, low tension pulse. The uterus was slightly subinvolved but otherwise appeared normal. I kept her in bed for a few days until her general condition had improved, and then did a subtotal hysterectomy. She had the most hypertrophied ovaries I have ever seen. Whitehouse has treated such cases by repeated curettage without success. He suggests partial excision of the ovaries, but does not quote any case which has been successfully so treated.

It is, however, about the menopause age (3) when the most trying and frequent cases of haemorrhage occur.

(a) In cases of cervical cancer, by the time the growth has developed sufficiently to produce considerable haemorrhage it is practically certain to be too far advanced for radical treatment.

(b) Bland-Sutton has suggested that uterine fibrosis is the cause of many cases of severe uterine haemorrhage at the menopause, and in a not very large percentage of uteri removed for this condition thick-walled blood vessels can be demonstrated.

(c) A condition much more frequently found is one which affects chiefly the endometrium, known as hypertrophic glandular endometritis, but the microscope does not usually show the small cell infiltration indicative of inflammation, and it would probably be more correct to regard the condition rather as a degeneration of the endometrium. The uterus is rarely much if at all enlarged. It may be retroplaced, but is more frequently in normal position. There is, as a rule, nothing abnormal found about the appendages. After removal the uterine wall is, on section, distinctly pale, but the obviously abnormal condition is an oedematous thickened endometrium, usually in places forming one or more mucous polypi from $\frac{1}{2}$ in. to over 1 in. in length. I

have hardly ever seen any blood clot in the uterus in these cases even when the operation has been undertaken as an emergency for severe active haemorrhage—which points, of course, to a probable deficiency of thrombokinase (blood-clotting substance).

(d) In other cases of irregular menopausal haemorrhage no abnormality is discovered in the uterus, either macroscopically or microscopically.

I think there can be little doubt that in all these cases, whether an obvious lesion of the uterine wall or of its lining membrane exists or not, the essential cause of the bleeding is an abnormality in the internal secretions. Some day we may learn how to regulate the functioning of these substances, but until we do I am strongly of the opinion that whenever the bleeding is so severe and so persistent as to make the patient's life a burden to her, the only certain means of curing her is to remove the uterus. Packing the vagina, curettage, ergot and similar drugs are most uncertain remedies and at best produce only temporary improvement. For beyond a doubt the patients who consult their doctors about bleeding of this sort as a rule never feel well; apart altogether from the haemorrhage there are symptoms, none of them perhaps very bad, but in the aggregate producing a sense of illness enough to make most women willing to risk operation in order to get rid of it, if they are not definitely discouraged by their medical attendant.

SOME DEDUCTIONS FROM THE STATISTICS ON THE PREVENTION OF PULMONARY TUBERCULOSIS.

BY

D. H. C. GIVEN, M.D., D.P.H.,
SURGEON COMMANDER, R.N.

Statistics show us that, in spite of all that has been said and done for the prevention of tuberculosis, our efforts in regard to pulmonary tuberculosis have not been attended with the anticipated success. The decline in mortality from this cause dates from 1838, and has continued steadily ever since down to 1913. Koch's discovery of the *tubercle bacillus* in 1882 does not appear to have affected it in any way. On comparison of the statistics of the four principal zymotic diseases (measles, scarlet fever, whooping-cough, diphtheria) with those of pulmonary tuberculosis, in the fifty years 1861-1910, we find the following decline:

Comparison in Deaths per Million Living.

	1861-70.	1871-80.	1881-90.	1891-1900.	1900-10.
Zymotics	2,061	1,633	1,367	1,219	999
Pulmonary tuberculosis	2,590	2,231	1,810	1,418	1,143

Representing a decline of 55.89 per cent. in zymotics and of 55.85 per cent. in pulmonary tuberculosis.

Comparing the average mortality per million living in the first six years of the period 1902-1913 with the last six years, in the air-borne diseases the following result is found: Pneumonia shows a decline of 14 per cent., phthisis of 11.6 per cent., bronchitis of 10.68 per cent., and the four principal zymotics of 21 per cent. Pulmonary tubercle is only one of the air-borne group of diseases. The chart below, prepared from the statistics of the Registrar-General for 1916, shows clearly that whatever the causes of these diseases, the same causes are common to the whole group. The death rates from the individual items that go to form the group show corresponding variations in different sections of the population. The curve of tubercle shows a slight deviation only from the other diseases of the group in the case of London and Southend, but I think this is explained from the fact that London is a big hospital centre, while Southend is one of our health resorts. It will be seen that for the whole of England and Wales and for the other sections of the population bronchitis causes a higher death rate than pulmonary tuberculosis.

We all know from experience that all these diseases are closely associated. The statistics show us that zymotic diseases expend themselves as regards fatality in the first fifteen years of life. Accounting for over 26 per cent. of

Air-borne diseases, representing three of the five principal causes of death in sections of the community. A Curve: Bronchitis, pneumonia, and other respiratory diseases. B Curve: Ditto, plus zymotic diseases. C Curve: Ditto, plus consumption.

curve of pulmonary tubercle, which, starting with 2.29 per cent. in the 1-5 age period, 10.43 per cent. in 5-15, reaches its maximum of 33 per cent. in the age period of 15-25.

The researches in regard to cerebro-spinal fever have done much to elucidate the problem of the source of respiratory infection. (BRITISH MEDICAL JOURNAL, September 18th, 1920.) It has been demonstrated how readily the meningococcus passes from throat to throat in an overcrowded community, and how rapidly it disappears with efficient ventilation and spacing out. The carrier rate rises twice as rapidly in the presence of sufferers from catarrh, so that for the prevention of outbreaks of meningitis it is more important to isolate the people suffering from colds than it is to isolate carriers.

Again, quoting from the *Australian Medical Journal* of June, 1920, in regard to the etiology of pneumonia, as the result of war experience, "Pneumonia is probably due to many factors, of which the association with persons suffering from catarrh is the most important." "Victor Vaughan found that the incidence of pneumonia among American soldiers in training camps fell when overcrowding and bad ventilation were removed." "Catarrh affects persons whose naso-faucial tissues are unhealthy. . . . A person with a normal nose and throat does not acquire a catarrh." The same probably applies to the "carrier" condition. Experiments to inoculate a healthy nasopharynx with pathogenic organisms, so far as they have been attempted, have been a failure. The healthy mucosa readily disposes of them. Again, what is bronchitis, which causes more deaths every year than consumption, other than an extension of the common cold where the resistance is low or where it has been reduced by repeated attacks? Over 20 per cent. of consumptives give a history of repeated colds in the head (Osler and McCrae). Putting two and two together, therefore, the common cold is probably the most important connecting link between all respiratory infections; it is the means of (1) disseminating air-borne disease, and (2) of preparing the soil for further invasions or for the condition of carrier.

In conclusion, I feel convinced that the campaign against consumption must be directed against the air-borne diseases as a whole, and against the common cold in particular. The effects of other respiratory infections, including the common cold and zymotic diseases, in early life is to prepare the soil for the later invasions of the tubercle bacillus when otherwise resistance should be high. The remedy for all these diseases is a matter of improved housing and education in ventilation and general hygiene, yet at the same time much could be done meanwhile by the more thorough recognition and treatment of the common cold and its sequelae.

THE RELATION OF TEMPERATURE TO THE ONSET OF A CARDIAC IRREGULARITY.

BY
R. MACNAIR WILSON, M.B., CH.B. GLAS.,
LATE CARDIOLOGIST TO THE WAR OFFICE TRENCH FEVER COMMITTEE.

Much has been written on the effect of temperature on the appearance of cardiac irregularity, and notably of the extra-systole. According to a number of observers there is a tendency for extra-systoles to disappear during high temperature, with a rapid pulse rate, after the manner in which they tend to disappear during exertion. Without any desire to controvert this view, which indeed is supported by much evidence, the following case is presented as affording in one direction a remarkable illustration of an opposite state of affairs, and possibly a sidelight on the etiology of this type of irregularity.

The patient, a young miner, was admitted on September 23rd, 1917, to the War Office Trench Fever Hospital, Hampstead, on the forty-second day from that on which he had contracted an attack of trench fever in France. When first seen he was suffering a typical relapse of this condition with headache, hyperalgesia of his shins, muscular pains in the legs and shin-bone pain. He himself was well able, from his experience, to diagnose what was wrong. His temperature was then 103° F., his pulse was markedly irregular, and a prolonged polygraph tracing was taken. It was found that the irregularity was itself singularly regular, an extra-systole ventricular type occurring every third beat. Only very occasionally were there

FIG. 1.

"runs" of regular rhythm; and these lasted for but a few seconds when they occurred, and then gave place to irregularity again.

FIG. 2.

The first tracing was taken at 7.10 p.m. At 9.20 p.m. the temperature had fallen slightly, and the pulse was 100, but the extra-systoles were less frequent. At midnight the temperature was 101° F., the pulse 100, and the extra-systoles less frequent still.

FIG. 3.

At 10 a.m. the next morning the temperature was 97.7, the

FIG. 4.

pulse rate 81, and there were no extra-systoles. The symptoms had markedly abated.

FIG. 5.

An interval of six days then elapsed, during which, so far as could be determined, there were no extra-systoles. On October 1st, however, the patient began to complain again, and took to his bed with a temperature of 102.5° F., and with a large number of extra-systoles—though not so regular an irregularity as on the first occasion. His pulse rate was 110. He had pains and aches

as on his first attack. Next morning he was well, with but an occasional extra systole, and no further notice of him was taken until three days later, when his temperature went up to 104°F .; pulse rate 110. He was now found to have a perfectly regular pulse, and he had no muscular pain, headache nor backache. He had, however, marked abdominal pain and diarrhoea. (In his former attacks he had been constipated.) His pulse is here shown. (Fig. 6)

FIG. 6.

From this point not a single extra systole was observed until October 15th, though the temperature remained high for a week, reaching normal only on the 12th. On October 10th rose spots appeared on the abdomen, and paratyphoid B was found bacteriologically to be present. The pulse rate did not rise above 100 after the first day; on October 8th it was 90, and on the 10th 75.

On October 16th slight pain returned to the legs, which had been quite free from this symptom—most unusually, as he stated—and a few extra systoles appeared. These continued off and on till the 22nd. On the 23rd his temperature again rose, and reached 103°F . on the 26th, but without pain or headache. He was sure this was not his trench fever, and had no extra-systoles. The pulse was 130. Temperature and pulse fell to normal on the 28th, and some extra systoles at once appeared. On November 1st, another attack with pain and headache came on, and this was accompanied by a few extra systoles.

The interesting point is that when they appeared the bouts of extra-systoles were always accompanied by trench fever symptoms, and that an exact eight day periodicity was

FIG. 7.—Heavy line = extra systoles per minute. Dotted line = temperature. A. Typical trench fever. B. Diarrhoea and abdominal pain. C. Trench fever pain. D. Abdominal pain, no trench fever pain.

shown in their onset. This is shown in Fig. 7. The temperature is also shown.

It is thus evident that the toxin of trench fever in this case produced a different effect on the rhythm of the heart from that produced by the toxin of paratyphoid B. Extra-systoles are relatively common in cases of trench fever.

THE HERPES-VARICELLA INFECTION.

BY

A. E. CARVER, M.D., CANAD., M.R.C.P. LOND.,
HONORARY PHYSICIAN, TORBAY HOSPITAL.

GENERAL recognition has as yet scarcely been accorded to the contention, which was first advanced by Böhay¹ of Budapest twenty nine years ago, and in support of which convincing evidence has been accumulating during the last few years, that herpes zoster and varicella own a common causal agent and are intercommunicable.

Further attention in this country was drawn to the association between these diseases by Dr. Le Feuvre in 1913, writing from Bulawayo. He reported nine cases in the *Guy's Hospital Gazette* and the *Medical Journal of South Africa*, in which varicella followed upon contact with herpes zoster; and others in which a varicella rash occurred in persons already suffering from herpes—the generalized rash appearing within five days after the appearance of the localized herpetic eruption. In this latter connexion he quoted a very pertinent observation by Adamson,² to the effect that in cases of herpes isolated vesicles may occur "sparsely scattered over all parts of the body," and suggested that this is in fact a scanty varicella eruption. It must be seldom that comprehensive search is made in a patient suffering from herpes for vesicles scattered over other parts of the body, but if this statement be generally corroborated it will constitute an

important link in establishing the contention that the two diseases are of identical origin.

Since Le Feuvre's first communication over fifty well authenticated cases have been reported in which varicella developed in persons who had been intimately associated with patients suffering from herpes zoster, and in each instance the probability of the infection having been contracted from other cases of varicella could be excluded.

Moreover, the interval between the appearance of the herpetic eruption in the one patient and that of the varicella rash in the other was within the recognized incubation period of the latter disease, or exceeded that period by no more than one day. Thus, in 51 cases in which the necessary dates and details are given this interval was:

10 days in	...	5	18 days in	...	1
12 "	...	1	19 "	...	5
13 "	...	1	20 "	...	1
14 "	...	13	21 "	...	3
15 "	...	2	22 "	...	1
16 "	...	4	"From 8 to 20 days" in 8		
17 "	...	1			

It is somewhat remarkable that of these 51 cases of varicella 8 were adults—rather a high percentage considering the infantile nature of the complaint.

In 1919 Dr. Cranston Low,³ in an illuminating paper rich in bibliography, concluded that these diseases are probably due to the same virus, and made the suggestion that in herpes zoster the infection spreads from the nose along the lymphatics to the olfactory nerves and the cerebro-spinal fluid; whereas in varicella it is probably a blood infection.

The following history of three cases which occurred in one family last autumn seems to be worth recording. Three children living in a country house were together in a tram on September 4th. This was the last occasion upon which they were away from home together in any enclosed or crowded place. On October 1st one child developed varicella at a school to which she had returned on September 22nd. On October 3rd, another child developed the disease at home, and,

on October 4th, the third child developed it at another school 200 miles away, to which she had gone for her first term on September 21st.

Clearly, the three children contracted varicella independently, yet from some common source; and seeing that they had not been about together excepting in the country during the twenty-seven days preceding the appearance of the rash in the first case, it was at first difficult to explain how this had come about. The two school children had been certified, in good faith, before returning to their respective schools, as having been in contact with no infectious disease during the preceding three weeks, and it was a matter of considerable annoyance to all concerned that two schools should have become infected through them at the beginning of the term.

Whilst staying in the house in which they had spent their holidays the children's grandmother had suffered a very severe attack of supraorbital herpes, of which the eruption began to appear on September 14th. To this patient the children had limited access, and, in view of the fact that contact with any case of varicella can be excluded, the suspicion is very strong that the herpes was the source of their infection. In these cases the herpes varicella interval was respectively seventeen, nineteen and twenty days from the first appearance of the herpetic eruption.

From the foregoing it appears that, sometimes at all events, herpes zoster is an infectious disease, contact with which is not rarely followed by varicella; but I have been able to find no recorded instance in which herpes in one patient has clearly given rise to herpes in another patient.

In all the cases that have been reported the varicella infection appears to have been contracted during the period of onset and development of the herpetic eruption, and no case has been reported in which it occurred as a result of association with herpes in its later stages. It is questionable, therefore, at what period of the attack the infection

from the herpetic person ceases to be communicable. From experience we know that varicella itself is highly infectious during the period of onset, and it is authoritatively laid down that persons suffering from varicella continue to be potential sources of infection until a new epidermic covering has spread over the site of the pocks, that is, until all scabs have separated, upon which precept practice is generally based; but until evidence is forthcoming that the period of infectivity similarly persists to the end of the attack of herpes, it would be unjustifiable to place a contact in quarantine until three weeks after the last herpetic scab had come away.

It must be admitted that the argument is not complete. Careful inquiry is necessary to elucidate the problem of where and how the herpetic infection is originally acquired. Then again, many cases of herpes zoster occur to which no spread of infection has been traced; and this raises the further question whether all cases of herpes zoster are in fact etiologically identical, or whether some are due to one infection, others to another infection, and others again to a process of a different category altogether.

MEDICAL, SURGICAL, OBSTETRICAL.

ASSOCIATION OF HERPES ZOSTER AND
VARICELLA.

IN view of the recent correspondence in the JOURNAL on the subject of the association of herpes zoster and chicken-pox, I think the following note may be of interest, and also helpful in making record of such cases.

On January 10th last Mrs. X. came to see me because of a rash on her body. This proved to be typical herpes zoster along the course of one of the upper left intercostal nerves. She asked me at the time if there were any fear of infecting anyone else, and I assured her that it was most unlikely, and that I had never known such a thing to occur in my own experience.

On January 25th—that is fifteen days after the herpes zoster appeared—I was asked to see the elder daughter. She had a temperature of 103° and a typical rash of chicken-pox. Some of the spots were well in the blister stage, and others were still coming out in crops at different stages. Three days later the younger daughter also developed typical chicken-pox. Both daughters had chicken-pox twenty years ago, the elder slightly and the younger more severely. To their knowledge none of the family had been in contact with any infectious disease. The incubation period of chicken-pox being usually eleven to fifteen days, it follows that had Mrs. X. suffered from chicken-pox instead of herpes zoster no one would hesitate to say that the daughters were infected from her. After the above experience I think it would be wise to be guarded in one's statements in regard to the possibility of infection from a case of herpes zoster.

A CASE OF TETANUS.

THE following case seems worthy of record, in view of the facts that: (1) there was, after the most careful scrutiny of the patient, and after investigation by the interpreter, no evidence or history of the minutest injury having occurred; (2) the case steadily improved, and finally recovered under treatment by the intramuscular method alone.

The patient (a German) reported sick to the medical officer in command of the prisoners of war compound in June, 1919, complaining of stiffness in the neck and feeling unwell. His temperature was not raised. He was "excused duty" and told to report next day. For the next three days he reported, but complained of nothing more than he did on the first day. On the evening of the fourth day he developed stiffness in the jaw and difficulty in swallowing, and was immediately sent to No. 42 Casualty Clearing Station at Douai diagnosed as (?) tetanus. On admission the patient had an anxious expression, risus sardonicus was present, trismus was very marked, and swallowing difficult. There was great rigidity and tenderness of the

muscles of the neck, the abdominal muscles were rigid and hard, the legs and arms rigid. Spasms were present, but not frequent, nor were they very severe; respirations were good. The temperature was 97° and the pulse 72. There was no evidence of cervical glandular inflammation, oral sepsis, carious teeth, or any other affection which might possibly give rise to the condition the patient presented.

Active antitetanic treatment was commenced at once, and within the first forty-eight hours of admission 52,000 units of antitetanic serum were injected intramuscularly. On the third day 8,000 units were injected, and for the next six days the daily dose was 9,000 units. On the tenth day no serum was given, and on the twelfth day a final dose of 1,500 units was injected, making altogether a total of 115,500 units administered in twelve days. The serum used was the concentrated form supplied by the Department of Hygiene, University of Toronto, a supply of which the A.D.M. stores fortunately had in stock at the time.

On the third day after admission the patient's temperature rose to 101°, at which level it remained more or less constant for seven days, when it gradually declined and became normal on the twelfth day. Constipation was very marked for the first five days, and required treatment. Sleeplessness and restlessness were also marked during the same period. By the seventh day the trismus was slightly lessened and the teeth could be just separated. From the eighth day onwards the trismus and muscular rigidity steadily diminished and the patient improved, until, on the twentieth day after admission, all signs and symptoms of the disease had disappeared. Shortly after this date the patient was up, and after a brief convalescence he was usefully employed for several weeks helping to look after the other German patients in hospital.

The outstanding features of the case may be summarized as follows:

1. No evidence of injury.
2. Rigidity of muscles of neck (later of abdomen and limbs).
3. Marked trismus.
4. No respiratory embarrassment.
5. Mild nature of convulsions.

The type of case should be classified as one in which trismus occurred after other signs of tetanus had shown themselves. Local premonitory symptoms occurred in the following order: (1) Pain (in muscles of neck); (2) difficulty in swallowing; (3) muscular rigidity.

Accidents due to serum were absent. There was no anaphylactic shock; there was no reaction, as shown by the temperature, to the injection of the serum in large doses, and there were at no time any signs of a serum rash appearing.

MASSAGE OF THE HEART AND RESUSCITATION.

I NOTICE that Professor Gunn, in his paper on massage of the heart and resuscitation (January 1st), expresses surprise that a mechanical pump is not used for artificial respiration in the human subject. I think that other anaesthetists will agree with me when I say that a pump for supplying intermittent inflation of the lungs is unnecessary. If a catheter is passed into the trachea with its distal end at the bifurcation, and if a continuous stream of air or oxygen (pure or etherized) is made to pass along it, the patient's colour will remain pink, and the pulse normal, even although no respiratory movements are taking place. This shows that there is sufficient interchange of gases to oxygenate the blood.

If, however, both pleural cavities are opened, and a very considerable pressure is required to inflate the lungs, it is necessary to let the pressure fall to zero from time to time, or the filling of the heart will be interfered with. Fortunately the number of operations in which this is necessary is small.

I have often thought that there are many other conditions in which insufflation of the lungs is indicated, but which until recently have been regarded as hopeless. For instance, a cerebral abscess or haemorrhage may have caused respiration to cease through increased intracranial pressure. If a tracheal catheter is at once passed, and the lungs inflated with oxygen, life may be maintained for a sufficient time for an operation to be performed.

A short time ago I was called to see a girl of 10 in extremis with bronchopneumonia and pericarditis. She was quite unconscious; the lips were purple, and she was giving about eight gasping respirations per minute. No carotid or radial pulse could be detected. I was struck with the similarity she presented to a deeply anaesthetized patient with a partially obstructed airway. In both there were two morbid conditions: (1) the obstruction, and (2) the toxin, which was chemical in one and bacterial in the

other. As soon as possible I passed a catheter into her trachea by means of a bronchoscope and turned on a gentle stream of oxygen. By this time respirations had entirely ceased; the pupil was dilated and fixed, and no corneal reflex was present. At the end of two minutes the colour of the lips was pink, the corneal reflex returned, and the radial pulse became palpable. This, I think, was the more remarkable as the girl had previously had pituitrin 1 c.cm., strychnine gr. $\frac{1}{16}$, and inhalation of oxygen with no effect whatever. At the end of five minutes a considerable amount of mucus had been blown out of the trachea, and the patient's condition was much better. Unfortunately the improvement was not maintained, and she died later; but I think that the result justifies the employment of this treatment in chest conditions where the right heart is obviously giving out from the effects of the toxin, the pressure, and the deficient oxygen supply; the latter factor can at any rate be remedied, while the respiratory obstruction can also be relieved to a certain extent by the mechanical removal of secretion.

Reports of Societies.

ACTION OF RADIUM AND X RAYS ON TUMOUR GROWTH.

At a meeting of the Royal Society, held on January 27th, with the President, Professor C. S. SHERRINGTON, in the chair, Sir WALTER FLETCHER communicated a paper on the "Local and generalized action of radium and x rays upon tumour growth," by Professor S. RISS, D.Sc., Dr. HARRY CHAMBERS and Miss GLADYS M. SCOTT. The paper recorded an investigation made with the object of finding the effects of the beta and gamma rays from radium and x rays upon rat tumours under varying conditions. The local effects were obtained by exposing the tumour only to measured quantities of radiation, the animal not sharing to an appreciable extent in the irradiation. When large doses were employed, destructive action upon the tumour cells was observed; as the dose was reduced, the action tended to become stimulative in character, so that the tumour cells grew more rapidly than they would had they received no radiation. The generalized effects of the rays used were obtained by submitting the whole animal to the radiation, the tumour in the animal being screened by the use of suitable screens. It was found that large generalized doses could not be borne by the animals; when, however, they were given repeated small doses an increase in body weight and an increase in resistance towards tumour growth was observed. Under the usual conditions of radiation treatment in malignant disease in man the body shared to some extent in the radiation administered to the tumour, and the bearing of the present observations in this connexion was discussed.

TREATMENT OF FRACTURES.

A GENERAL meeting of the Border Counties Branch of the British Medical Association was held at the Lowther Hall, Carlisle, on January 14th, at 3.30 p.m. In the unavoidable absence of Dr. Livingstone, the Branch president, Dr. BOWSER of Penrith took the chair.

Major MELNIE SINCLAIR, C.M.G., R.A.M.C., gave a lecture on the treatment of fractures, and illustrated his methods by showing patients who had been put up in the splints used for the various fractures of the upper and lower extremities. The principles which governed the choice of the apparatus and the mode of application were thoroughly explained in each case. After a short interval for tea Major Sinclair showed a set of x ray lantern slides of fractures which he had treated. A most cordial vote of thanks was passed to him on the proposal of Dr. CULLEN, seconded by Dr. CLERKE. Between sixty and seventy medical men and nurses were present.

A joint meeting of the Midland Branch of the British Medical Association and the Nottingham Medico Chirurgical Society was held on January 20th, when, by permission of the Director General of the Army Medical Service, Major SINCLAIR gave a demonstration at the General Hospital, and a lantern lecture at the Medico Chirurgical

Society's rooms, on fractures of the femur. Major Sinclair brought with him fifteen of his modifications of the Balkan beam, and the splints were shown in position on patients. The lecturer briefly described the Thomas splint and the principles of its action, and then showed a method of applying the splint as a first aid treatment, in which an iron shaver inserted through the boot upper close to the sole was used as an attachment for extension, and the splint was slung to metal frames attached to the sides of the stretcher. The Thomas splint was then shown as used for the treatment of fractured femurs, and the lecturer emphasized the necessity (1) of preserving the normal forward arch of the femur; (2) of maintaining the foot in a position of eversion during the treatment; (3) of bending the splint near the knee joint, especially in fractures of the lower third of the femur. The value of the treatment was explained and shown.

For cases which did not respond to ordinary extension with flannel and Sinclair's glue, the lecturer advocated extension by screws inserted into the upper end of the shaft of the tibia, and explained their advantages over callipers applied to the femoral condyles. He maintained that no permanent disability resulted from stretching the ligaments of the knee joint by extension applied to the tibia. At the close of the demonstration the lecturer showed his various modifications of the Thomas arm splint and his special splints designed for fractures of the wrist and hand. The results shown were very striking, and at the close of the lecture the thanks of the Society and the Association were voted by acclamation to Major Sinclair for his practical and interesting demonstration and lecture. The demonstration and lecture were repeated on the following day for the nursing staffs of the general and neighbouring hospitals.

As a result of this demonstration it is expected that the various collieries and ambulance stations in the county will be equipped with Thomas splints for first aid treatment of fractures of the lower extremity.

Reviews.

PHYSICAL SIGNS.

In his well written manual *Physical Signs in the Chest and Abdomen*, Dr. A. J. JEX BLAKE¹ has successfully carried out a task that is more difficult than the elementary nature of the subject matter might at first sight suggest, of such manuals being indeed hard to make attractive, often prove dull to the reader. Those who gain the basis of their knowledge of physical diagnosis under Dr. Jex-Blake's direction will do so with greater ease and interest than fell to the lot of some of their seniors; for the text is not a mere recital of stereotyped physical signs, but is brightened by occasional touches and practical hints, shrewd and even slightly whimsical, and contains remarks on the interpretation of the signs set forth in a manner showing the independence derived from a long experience in teaching. Thus variations from the normal, such as dilated venules on the chests of emphysematous persons sometimes regarded as of pathological significance and even dignified by a special Latin name, which have no important bearing, are mentioned only in passing. The use of the sphygmomanometer, polygraph, electrocardiograph, and x rays is not described, on the ground that these methods are not, as a rule, available for the individual student or practitioner of medicine; as regards the blood pressure estimation, this decision appears to be one that might be reconsidered when revision for a second edition becomes necessary, for in this respect the sphygmomanometer is hardly on the same plane as the electrocardiograph.

The work is divided into three parts; more than half the book is devoted to the examination of the chest, which is followed by a description of the physical signs of intrathoracic disease, and then by the section on the examination of the abdomen and an account of abdominal swellings. Under the heading of palpation, testing for superficial tenderness appropriately finds a place with a table of the chief cutaneous areas in which referred pain and super-

¹ *Physical Signs in the Chest and Abdomen*. By A. J. Jex Blake, M.A., M.D., F.R.C.P. London: J. and A. Churchill, 1921. (Demy 8vo, pp. 119, 27 figures. 5s. 6d. net.)

sional tenderness occur in visceral disease, and of their innervation; attention is drawn also to Dr. H. Head's observations on the reflex headaches and tenderness of the scalp secondary to disease of any of the thoracic or abdominal viscera. The appearance produced in the lower part of the abdomen by a distended urinary bladder is compared to that represented in Donatello's statue of David; this condition is said to reproduce, on percussion, the thrill characteristic of a hydatid cyst.

A CONSULTING SURGEON IN THE NEAR EAST.

THE record of Mr. Tubby's experiences as a consultant in the Near East² will have an interest—a melancholy one in some cases—for those who served with the Egyptian and Dardanelles Expeditionary Forces during the earlier years of the war. He has portrayed in a highly tolerant spirit the conditions under which medical and surgical aid was brought to the sick and wounded during these strenuous years. He records much that might have been bettered had the magnitude of the task which the landing in Gallipoli involved been more fully appreciated. He finds much to excuse and no little to admire in the gradual evolution of order out of chaos. That the consultant surgeons in the theatre of war had much to do with the improvement in the character of the surgical relief afforded to our troops there can be little doubt from Mr. Tubby's record, but one reads with some surprise that for more than a year the services of consultant physicians were not made available for the assistance of hospital and administrative authorities. This is all the more remarkable in view of the fact that so many officers of the Indian Medical Service—whose experience of tropical maladies is unrivalled—were at that time serving in the Near East.

The deplorable dearth of x-ray apparatus during the year 1915, at a time when they were most urgently required, was a matter that aroused the deepest concern on the part of all surgeons. Sir Victor Horsley from the moment of his arrival in Egypt had agitated for immediate action in this matter. We learn, therefore, with surprise from Mr. Tubby's narrative that it was not until the lapse of several months that the steps taken by the consulting surgeons to secure the proper provision of these indispensable aids to surgical diagnosis and treatment were at length attended by success.

Mr. Tubby's narrative of events in Palestine, and his comments on the duties, rank, status, and emoluments of the consultant surgeon, will be read with interest. The book is provided with a double index—one of names and one of subjects. It has a number of interesting illustrations. As a record of work attempted and achieved the book is of value. From its perusal one gains the impression that the consultant surgeon of the future should be one to whom the quotation with which Mr. Tubby opens his fourteenth chapter applies—"Now Mr. Great-Heart was a strong man, so he was not afraid of a lion."

AN ABSTRACT OF UROLOGY.

THE *Précis d'Urologie*, by FÉLIX LEGUEU and EDMUND PAPIN,³ fulfils admirably the purpose for which it was written. The work is well named; it is a *précis*—concise, clearly written, and excellently illustrated. Altogether it is a work worthy of its eminent authors and of the distinguished school of urology to which they belong. In England genito-urinary surgery is apt to be regarded still as an appendage of the general surgeon, and for this reason an English school of urology does not exist; consequently French textbooks on this subject are of especial importance to English practitioners.

The work under review has been divided into three parts: the first deals with methods of examination, the second with signs and symptoms, and the third with the pathology of diseases of the genito-urinary apparatus. The surgical anatomy introduced into the first part is done with extreme thoroughness, and the pictures are unusually good. This excellence in illustration is, however, by no means confined to surgical anatomy. The graphic method of representation has been lavishly utilized throughout. It

would be possible to review rapidly the whole of genito-urinary surgery merely by running through the illustrations to be found in this book without even referring to the text. For example, the various complications of such a complaint as senile enlargement of the prostate are represented in diagrammatic form. Lengthy descriptions are thus avoided, and a clearer and more lasting impression of the subject is conveyed to the reader. The work is not encumbered by historical references or bibliographies, and thus retains throughout its character as a practical *précis*; but for the benefit of those to whom it would be useful, a bibliography is appended at the end.

In their preface the authors state that they have written for the student and the practitioner alike, but the amount of information they have supplied would certainly seem to be sufficient to satisfy also the needs of those who specialize in genito-urinary surgery. Were it not for the fact that the majority of those who have taken up the study of this branch of surgery in England can read French we would urge that an English translation of the work should be prepared. While we retain our appreciation of the larger treatise on urology previously published by Professor Legueu, we believe that this *précis* will meet with a still greater success, and prove itself a still more useful publication.

AN AMERICAN MANUAL OF PSYCHIATRY.

THE popular *Manual of Psychiatry*,⁴ of which Dr. A. J. Rosanoff is the editor, has now reached its fifth edition. The volume first appeared in 1905 as a translation of the French textbook by Dr. J. Rogues de Fursac, and anyone who is in doubt as to the progress of psychiatry during these fifteen years would do well to compare the first and fifth editions of this manual. It is especially made evident in the present edition, which contains several new chapters, that psychiatry is no longer a narrow speciality, the activities of which are confined to the institutions for the insane. Not only has it a vital and necessary relation to medicine as a whole, but it finds increasing points of contact with schools and social organizations concerned with the all-important problems of mental hygiene. A special chapter is devoted to psychiatric social work, especially in relation to the training of the social worker and the development of a social service department in hospitals for mental disorder. It is impossible to avoid the reflection that in such directions America is a good deal ahead of this country, and is more fully alive to the needs of the community in respect to the extramural applications of psychiatry.

The attention given to the practical side of psychiatry in this volume may be favourably commented upon. The appendices containing descriptions of the technique of lumbar puncture, cell counts, and chemical tests will be found most helpful to the student and practitioner, and perhaps even more so the seventy pages devoted to a detailed account of the Stanford Revision of the Binet-Simon Intelligence Scale. Much skill and experience is certainly necessary to apply these tests usefully. They contain numerous pitfalls for the unwary, and the instructions herein included would do much to prevent errors. Dr. Rosanoff devotes seventy-four pages to the free association tests (Kent-Rosanoff), a subject in respect to which he is responsible for much original work. The frequency tables will be found of value to those who are specially interested, but the amount of detail given is perhaps in excess of the needs of students.

The chapters concerned with symptomatology and the various clinical groups are not so expressive of more recent developments as are the sections relating to the wider fields into which psychiatry has now extended. The author's treatment is mainly descriptive, and he does not attempt any psychological interpretation of abnormal reactions. An exception is made, however, in the case of hysteria, where attention is devoted to the psychic mechanisms of the disorder. The discussion upon the distinction between hysteria and malingering is vigorous in tone; the tendency to differentiate these conditions on the basis of the conscious or unconscious quality of the motivation is strongly criticized; and there is a good deal

² *A Consulting Surgeon in the Near East*. By A. H. Tubby, C.B., C.M.G., M.S. Lond., F.R.C.S. Eng. London: Christophers. (Demy 8vo, pp. xiii + 278; illustrated. 15s. net.)
³ *Précis d'Urologie*. By F. Legueu and E. Papin. Paris: A. Maloine et Fils. 1921. (Demy 8vo, pp. 709; 479 figs. Fr. 50; post free, Fr. 55.)

⁴ *Manual of Psychiatry*. Edited by Aaron J. Rosanoff, M.D., Clinical Director, King's Park State Hospital, N.Y. Fifth edition, revised and enlarged. New York: John Wiley and Sons; London: Chapman and Hall. 1920. (Post 8vo, pp. xv + 664. 25s. net.)

to be said for the view that this vague and subjective criterion "should not seriously occupy the professional mind as a guide in practical work." The author expresses the opinion that the difference is entirely one of viewpoint. Hysteria is a term stressing the medical view-point and malingering the legal. His opinions as to the motivating factors in the production of hysterical symptoms are expressed with considerable frankness, and a somewhat unflattering picture of the hysterical personality is drawn.

A chapter is devoted to psycho-analysis. It chiefly consists of selected passages from the works of Freud. There is no evidence, however, that Freudian views have to any extent influenced the psychiatric outlook of the author. There are numerous other additions in this volume besides those to which reference has been made, and it may be regarded as having been brought thoroughly up to date. There is no doubt that it will continue to maintain the reputation it has had in the past as a sound and trustworthy textbook, including within a reasonable compass the main facts which the student and practitioner require to know.

SYPHILIS, ESPECIALLY OF THE SKIN.

In *Syphilis and its Treatment*,⁵ by Dr. WILFRID FOX, the author has written with special reference to syphilis of the skin. Indeed, in our opinion, he would have done well to indicate definitely in the main title of his work that it had been written from the standpoint of the dermatologist rather than that of the syphilologist. The book is the outcome of work done in the venereal and dermatological departments of St. George's Hospital and the Seamen's Hospital at Greenwich. It is intended for the use of medical students and practitioners of medicine.

By far the best chapters are those dealing with cutaneous lesions; this subject is well illustrated, and the plates are very clear. The author has given an excellent description of the various forms of rashes met with in the secondary stage of syphilis, and his paragraph on psoriasisiform rashes is good. The table of the various points which enable papulo-squamous syphilides to be distinguished from psoriasis is especially useful. The paragraphs dealing with syphilis of tissues other than the skin and mucous membranes are, on the whole, disappointing, and the same must be said of the chapter on treatment. If intended for the use of students, this chapter should have contained at least one or two illustrations in order to render it clearer. It is difficult for a specialist in writing a textbook on syphilis to avoid giving a false impression of the relative importance of its protean manifestations. Whilst many pages have been devoted to the subject of cutaneous syphilis, only a few paragraphs have been spared for the infinitely more important subject of neuro-syphilis. For this reason Dr. Fox's book must tend to give the student an impression that cutaneous lesions rather than lesions of the central nervous system are the most serious manifestation of the disease.

In dealing with the treatment of congenital syphilis the author speaks in a rather half-hearted way of the use of the salvarsan preparations. Intramuscular injections of galyl he is inclined to consider too painful for so young a subject as an infant; in older patients, whenever a suitable vein can be discovered, he suggests the adoption of the ordinary methods of intravenous injection. In our opinion the results recently obtained from the use of arsenical preparations in congenital syphilis are sufficiently good to justify its routine use in such cases. The insertion of the final chapter on syphilis and public health is to be welcomed. The more fully the medical profession becomes acquainted with the importance of venereal disease as a factor in public health, the more likely is the subject to receive the attention and consideration that it merits.

As we have indicated, Dr. Wilfrid Fox has written an excellent work on the cutaneous manifestations of syphilis, but he has not succeeded so well in his attempt to make it a general treatise on syphilis.

⁵ *Syphilis and its Treatment: with Special Reference to Syphilis of the Skin.* By W. S. Fox, M.A., M.D., B.C. Cantab., M.R.C.P. Lond. London: H. K. Lewis and Co. Ltd. 1920. (Roy. 8vo, pp. 203; 39 figures, 15 plates. 3s. net.)

THE SCHOOL OF SALERNUM.

The increasing number of lovers of medical history will welcome the appearance of the volume containing, in addition to Sir John Harington's English version (1607) of the *Regimen Sanitatis Salernitanum*⁶ and the Latin text used by Sir Alexander Croke, two interesting introductory articles by Dr. F. R. PACKARD on the history of the school at Salerno, and by Dr. FIELDING H. GARRISON on the pre-history of the *Regimen Sanitatis*. There are also critical notes on the texts of the poem. Dr. Packard accepts the view, and quotes Croke's arguments in favour of, the widely accepted belief that the poem was composed for Duke Robert, the eldest son of William the Conqueror, who visited Salerno to obtain treatment for a poisoned wound. Dr. Garrison, however, follows Sudhoff, who rejects this tradition and traces the poem to a prose hygienic epistle supposed to have been written by Aristotle for the benefit of his pupil Alexander the Great, and translated into Latin at the beginning of the twelfth century by a baptized Jew, John of Toledo. Dr. Packard admits that the authorship is doubtful, but appears to accept Croke's opinion that it was written by John of Milan, who is supposed to have been the head of the faculty of the Salerno school at the time. In this connexion it may be mentioned that in his scholarly history of this poem in the first Finlayson memorial lecture (1908) Sir Norman Moore came to the conclusion that the author is unknown. Dr. Packard's interesting sketch of Sir John Harington, who in addition to being one of the most characteristic of the Elizabethan courtiers, invented and described the modern water-closet, in "A new Discourse of a stale subject called the Metamorphosis of Ajax" (London, 1596), recalls Dr. J. G. Adams's attractive essay on this many-sided Cambridge graduate.

The poem is a handbook of domestic medicine; it was much in request, and, as was so common in the days before printed books, became much altered in the course of many copyings, successive scribes adding to it at their discretion; thus the early copy commented on by Arnold of Villa Nova contained about 363 lines, but subsequently it became expanded to over a thousand lines. It provides advice on diet, personal hygiene, and remedies, and ends on the cheerful note:

And ye our Physicke raies that friendly read,
God grant that Physicke you may neuer need.

Like other publications from P. B. Hoeber, this volume is well printed and successfully illustrated.

NOTES ON BOOKS.

A FIFTH edition has just been published of Dr. J. RYLAND WHITAKER's book on the anatomy of the central nervous system.⁷ Dr. Whitaker is well known to many generations of Edinburgh students and Fellowship candidates as a singularly gifted teacher of anatomy, with a rare talent for clarity of exposition of the most intricate subject. This faculty is reflected in the present volume, the popularity of which is shown by the number of editions published, although it was once out of print for some years. The book is not long, but it is very complete; any increase in length over that of previous editions is due to rewriting with the object of rendering obscure passages easier to understand. The brief summaries and tables are an aid to quick and easy reference, and the excellent illustrations and diagrams fulfil their purpose of increasing lucidity where necessary. Dr. Whitaker talks of growing old, and if ever he does retire—though that seems impossible to old Edinburgh students—this book of his, filling a place peculiarly its own, will certainly keep his memory green.

Dr. A. S. GUBBE, of Mustapha Supérieur, Algiers, has published, under the title *From Cloud to Sunshine*, a new edition (the tenth) of his notes on Algiers and Algeria as a winter resort, which he first published some years ago. It is not exactly a guide-book but an impressionist sketch,

⁶ *The School of Salerno—Regimen Sanitatis Salernitanum.* The English version by Sir John Harington; History of the School of Salerno, by Francis B. Packard, M.D.; and a note on the Pre-History of the *Regimen Sanitatis*, by Fielding H. Garrison, M.D. New York: Paul B. Hoeber. 1922. (Demy 8vo, pp. 214, illustrated. 5s. 7d.)

⁷ *Anatomy of the Brain and Spinal Cord.* By J. Ryland Whitaker, M.B., F.R.C.P. Fifth edition. Edinburgh: E. and S. Livingstone. 1921. (Post 8vo, pp. 262; 103 illustrations. 12s. 6d. net.)

well illustrated by photographs. In addition to Algiers itself and Hammam-R'irha, there are short notes on many more distant places to which agreeable excursions can be made. The book appears to be issued for private circulation, as no publisher is mentioned.

THE anonymous author of *Memories and Musings of a Hospital Surgeon*⁸ has spent nearly fifty years in hospitals—as a student in London, as a house-surgeon, as an operating and consultant surgeon, and as a hospital governor. He is therefore well qualified to discourse to the layman of hospitals past and present, of patients and children, of operations and treatment in general, of medical education and the future of hospitals. He has little that is new or original to say, but in a manner of amiable rotundity—a compound fracture is described as having “an open wound leading down to the broken bone, thus exposing it to the deleterious influences of external agents”—he gives us, unconsciously, a self-portrait of a surgeon of the older generation. The author's allusions are to his own experiences, to the masters of his own craft, and to the Bible; he is a personal friend of all his poor hospital patients; his character is founded upon his early religious convictions.

We have received the thirty-sixth edition of *Sell's World's Press*,⁹ which forms an accurate and comprehensive directory to the periodicals published in this and other countries. The editor in his foreword records that, owing to the enormous increase in the cost of production, many old and valuable publications have now ceased to exist, while during the past year more than 500 have been forced to increase their selling price. The present edition of this useful directory, with its 35,000 entries, is introduced by a number of articles of interest to those concerned in newspaper production, by, among others, Lord Northcliffe, Mr. Robert Donald, and Mr. H. W. Massingham.

⁸ *Memories and Musings of a Hospital Surgeon*. Glasgow: Maclehose, Jackson, and Co.; London: Macmillan and Co., Ltd. 1920. (Cr. 8vo, pp. 198. 7s. 6d. net.)

⁹ *Sell's World's Press*. Founded by Henry Sell. Thirty-sixth edition. Edited by E. T. Brown. London: Sells, Ltd. 1921. (Roy. 8vo, pp. 153; illustrated.)

APPLIANCES AND PREPARATIONS.

An Outfit for Immediate Treatment of Cases of Poisoning.

DR. C. A. STIDSTON (Wolverhampton) writes: An examination of the reports of the Registrar-General for England and Wales alone, for the years 1901-1918 inclusive, reveals the fact that during those eighteen years more than ten thousand deaths have occurred from poisoning, caused by accident, negligence, suicide, or murder. Nearly eight thousand five hundred of these deaths were suicidal. There are no means of estimating how many additional cases of poisoning occurred with recovery, but institutional and private practice justify the assumption that the number of cases that recover greatly exceeds the number of cases that prove fatal. Hence it appears that poisoning is a serious cause of death and illness, and its treatment at the earliest moment is a matter of importance.

Whilst the poisons chiefly taken are commonly known and easily accessible—such as carbolic acid, which caused 1,740 of the deaths quoted above; oxalic acid, which caused 1,439; hydrochloric acid, which caused 1,249; and opium derivatives, which caused 1,062—the following list (compiled from the reports) shows how extensive and varied are the possible sources of fatal or non-fatal poisoning:

Acetic acid; acetanilide; aconite plant; ammonia; aniline; antimony chloride; aspirin; atropine sulphate; A.B.C. liniment; ammoniated tincture of gualacum.
Barium chloride; belladonna; berries of laurustinus, deadly nightshade, ivy, laburnum.
Chloroform; chloroform; cocaine; coal tar; chromic acid; camphor; copper sulphate; chloride of lime; creosote; camphorated oil; caustic soda and potash; chloral hydrate; cresolene; carbolic acid; coal-tar naphtha; colza oil.
Daisies; daisy; Dutch drops.
Ether; eser.
Formalin.
Gaultheria oil.
Hartsborn oil; hyoscyamus.
Iodine; insecticide.
Lysol.
Methylated spirits.
Nepenthe; nicotine; nitre; nitric acid.
Paraffin; paregoric; potassium chlorate, oxalate, permanganate, bromide, binoxalate, and chloride; petrol; phosphorus; paraldehyde.
Quinine.
Red precipitate; rhubarb leaves.
Sodium nitrate; salts of lemon; sulphonal; sheep foot-rot dressing; soldering fluid; soap liniment; sulphuric acid; solanin; sal volatile.

Thymo-cresol; tartar emetic; trional; toxal.
Veronal; vermin destroyer.
Wood spirit; weed-killer.
Yew berries.
Zinc sulphate.

A summons to a case of poisoning is often a cause of bewilderment and dismay to a medical man. He hurriedly tosses a few chance emetics and antidotes into a bag, often owing to the scanty information offered by the messenger, omitting the items essential for dealing with the particular case. The stomach tube is not to be found; the hypodermic case is, perhaps, at the bottom of the midwifery bag, the book on toxicology is lost. To complete the outfit a futile attempt is made to reach an inaccessible chemist, and a delayed arrival finds the patient beyond treatment or only fit for transfer to a distant institution, there to succumb and await the coroner's court. Clearly it is advisable that an outfit containing emetics, stimulants, antidotes, and apparatus for emptying the stomach should be in the possession of every medical practitioner and should be available in the first-aid rooms of works, in police stations, and in the casualty departments of hospitals. This need having been recently and painfully brought home to me by personal experience, I have designed an outfit to prevent delay in future cases. It consists of a small, easily portable, japanned tin case, which opens portmanteau-wise and which, to avoid the tragedy of the lost key, possesses no lock. The contents of the case are all displayed when it is opened, and consist of the following:

Stomach tube and rubber funnel; a smaller tube for children.
Gag to open mouth; gag to pass tube through.
Tongue forceps.
Record hypodermic syringe.
Murrell's book, *What to do in Cases of Poisoning*.
Hypodermic tablets: Apomorphine hydrochlorate, strychnine nitrate, atropine sulphate, morphine tartrate, aconitine, pilocarpin nitrate, digitalin.
Capsules of amyl nitrite.
Pituitrin.

The following in two or four ounce glass-stoppered bottles—with dosage on labels:

Zinc sulphate; sodium chloride; mustard; brandy; coffee; tea; sal volatile; wood charcoal; permanganate of potash; dialysed iron syrup of chloral; magnesia; potassium bromide; chloroform; sodium carbonate; sodium sulphate; magnesium sulphate; vinegar; tincture of opium; olive oil; castor oil.

Spare bottles.

This outfit has been made and furnished by Messrs. Philip Harris, chemists, of Birmingham.

Nasal "Aseptoids."

WE have received from Messrs. Oppenheimer, Son and Company, Ltd., a sample of "aseptoids" nasal compound, prepared from a formula by the late Dr. Macnaghten Jones. The ingredients are moulded without compression into square-shaped tablets, readily soluble in warm water for use as a gargle or nasal douche; their uncommon shape and appearance make it unlikely that they would be mistaken for medicinal tablets and swallowed.

THE DIARY OF CROSSE OF NORWICH.

THE diary of Bob Sawyer would have been interesting reading. *Mutatis mutandis*, it would have run somewhat on the lines of the well known "Diary of a Resurrectionist," and would have been, in part at least, a record of drinking bouts with Mr. Allen and the Pickwickians. It would not, however, have been a fair representation of the life of medical students then. A hundred years ago there were at least three types of medical students—the Sawyers and Allens, the hard-worked and ill-fed apprentices, and the select class who paid premiums to teachers of repute, and may be said to have been young men with a future. To the last-mentioned category belonged John Greene Crosse, afterwards well known, and now still quoted as "Crosse of Norwich."

Born in 1790 of yeoman parentage in Suffolk, Crosse was well educated by a hard-working father, and never really sank below the line of self-respect and well-being. It was not till he had reached the age of 29 that he, then in practice in Norwich, procured a book with a view "of filling a few of its pages from time to time with memoirs." This was in continuation of his boyish diaries. As became an accomplished practitioner, he now aimed during his remaining life at amassing materials for a classic work on surgery, and "should aspire to no higher pitch of posthumous fame than to have a few memoirs of my life prefixed to my work, in order to show how industrious habits are their own reward, and how obscurity of birth

and disadvantages in education are overcome by steady and honest perseverance."

After this formidably meritorious opening, which suggests a reflection by Herbert Spencer, we meet with this quaint vignette: "I can well remember, when a child put out to nurse in a humble cottage near my father's, that the old lady, of ominous name, *Goody Death*, during a thunderstorm, used to read her Bible in great fear, and offer prayers to appease a justly offended God, humble and contrite for her manifold sins; and I by her side joined her as far as my age would allow in fear and prayer." He lived to find out the secret of summer storms as purifiers of the air and fertilizers of the soil, and to take the then optimistic view of natural phenomena. He was not sent to boarding-school, and for this reason is of opinion that he contracted lifelong unsocial habits. Reading, writing, and arithmetic he learned from a horrifying master. "His stern brow, raucous voice, and long cane, are now lively depicted to my mind." When Mr. Crosse was in his twelfth year, "a Welch gentleman making some mistake at college (not implicating his good character, an *informality* I should call it) found it well to rusticate." Indeed, Mr. "Jones of Jesus," as we will call him, married while still an undergraduate, and was compelled to open a school for a living. The little boy was one of his first pupils. Mr. Jones was "a plodding working man," and an increasing family goaded him into being an excellent teacher. To him Crosse owed a knowledge of Latin and Greek, and laid the foundation of remarkable linguistic attainments under his mild rule. At the age of 15, on his way home from school he tried "a feat in jumping" and broke his leg. "The respectable village surgeon attended me: he was one of the old school; of fine, soft, soothing manners. Clean dressed, with powdered head; rode slowly a very well-looking horse; in short, he was a gentleman, and commanded the respect of everyone when he entered the house; he was also a skilful and kind surgeon. What wonder that the idea should be awakened in my mind to be of the medical profession! to be as great a man as he—the Village Doctor! to whom everyone bowed, and who could relieve pain and cure injuries so quickly and skilfully. I had conceived an object of ambition, and the idea never deserted me. I was in a month upon my crutches and soon recovered; a surgical case fixed my future destinies."

For a time, however, after finishing his study of Latin, Greek, French, and Euclid, he was in a lawyer's office and did not like his work. He attended bankruptcy meetings and feasted "at midnight at the expense of the already distracted creditors. Those were good times for lawyers. A learned chancellor, whom I met on one such occasion, I well remember complimenting me on my quickness in counting money; but all would not do, my mind was pre-possessed—I quitted the law to follow my inclination; I made my own choice; it was a pledge to success. The surgeon who cured my leg agreed to take me as his first and only pupil, and I was accordingly articled in due form for five years."

He took up his residence with Mr. Bayly of Stowmarket, bought a book, and wrote on the title-page: "Hic liber a Johanne G. Crosse febat. Augusti 8vo, Anno Domini 1806. On Wednesday, April 3rd, 1805, I broke my leg."

The first entry in the diary runs thus: "Die lunae Augusti 18, 1806. Came to Mr. Bayly's. Rolled up pills, etc." There follow accounts of daily routine. He goes to bed at ten or eleven o'clock, rises from six to eight. On August 27th he "did up a man's leg before Mr. Bayly was up, for the first time. Made a pledget and put it into a boy's ankle. Made 39 pills in the afternoon." His first surgical operation was the drawing of a tooth. Later he went with Mr. Bayly to see Martin Chenery's leg, which was hollow. "Mr. B. ran a silver pin in three inches, and a matter came out."

This first volume ends on January 31st, 1809, and he has then been to many balls and music parties and has lived a civilized life. There is a charming Miss Bayly, who afterwards becomes his wife. Volume II is much more profound, and we find him a deep and careful student of general literature. He reads a *Life of Malesherbes*, the advocate and friend of Louis XVI. "His wisdom I admire, his piety, his liberality, his courage; he was the foe of tyranny, the encourager of learning, the defender of the oppressed. . . I will endeavour to imitate so virtuous a character, and I pray for the

assistance of Almighty God." He reads Corneille and religious books, and plays a good deal of whist. "I would never trifle so much as to play were it not to please; he has obtained a great point in the art of pleasing who has learnt to trifle well." England being then in the throes of war with Napoleon, he reflects sagely on the proper conduct to observe during times of stress. "It behoves us at all times to keep from every wicked thing, but more especially in time of war and danger." The war is responsible for strange social reverses. "A woman came begging here to-day who was, or had been, mistress of French and music; she says she had a good education and had lived in high life, but a series of misfortunes reduced her to the necessity of begging her bread in her old age. I heard her play on the piano, and though long out of practice and her fingers stiffened by labour and fatigue she showed some knowledge and execution. French she could speak as fluently as English."

Crosse wrote two more volumes of reflections and daily occurrences, the fourth glancing at his early career as a student at St. George's in 1811-13. He became the pupil, and later the lifelong friend, of Sir Charles Bell. In 1812 he studied under him and under Brodie, Brand, Clarke, and Home, and remarks in his journal, "Very industrious all this winter, sitting up constantly till past two a.m." Throughout life he was an ardent student, a man of an intensely earnest character, yet vivacious and joyous in spirit. He became famous as a lithotomist in a district where calculous disease was endemic. As an operator he had few rivals, and his students delighted in his teaching. He died worn out by the multiplicity of his activities at the age of 60. He had burnt the candle at both ends for many years, during which he took notes of all important cases in his public and private practice, wrote and read professional works voluminously, lectured, operated, rode long distances to attend *post-mortem* examinations, and at night, after an exhausting day, would, after listening to a little music, spend many hours in literary pursuits, "trusting to a change of occupation for relief and amusement" rather than to the rest that was so necessary for him. He set a bad if high example, but one that only the few were likely to follow.

Perhaps his best known work is his Jacksonian Prize Essay, "On the Formation, Constituents, and Extraction of the Urinary Calculus." For this he received the diploma of M.D. from the University of Heidelberg, and the year after was elected F.R.S. The original MS. of this important essay, together with his drawings, are in the library of the Royal College of Surgeons. The work was published in 1841; it had three appendices, one of which contains an exhaustive bibliography of calculi and lithotomy. This alone bears lasting witness to the vast extent of his reading. It contains his portrait, showing a nervous, over-intellectual face. VICTOR G. PLARR.

THE CINEMATOGRAF.

THE multiplication of "Picture Palaces" must be patent to everyone, but few who have made this observation will know what an immense industry there is behind these small and gaily decorated places of entertainment. The production of a film is a very great business. Thousands of actors and actresses are engaged in the work of production in this and other countries, and an examination of a Stock Exchange list will show what a large amount of capital is employed in these ventures, not taking into account the resources of private firms. Until recently little has been heard of the studio side of the industry, excepting an occasional newspaper paragraph that such and such a firm had produced some wonderful film of many thousand feet necessitating the engagement of some hundreds of actors and the expenditure of thousands of pounds. The statements seem like fairy tales, but they can well be believed when the inside of a good-sized studio is seen. Recently other interests have been added from the medical point of view. Dr. Chappé, writing in the *Annales d'Oculistique* in July, 1920, under the title of "Conjunctivite chez les Artistes du Cinéma," stated that cases had been observed in which exposure to the brilliant artificial illumination of the studios had produced attacks of pain and conjunctivitis of transient duration. An earlier account in a trade journal stated that several members of a film company were affected by semi-blindness,

On January 18th of the present year a meeting was held by the Society of Illuminating Engineers, at which a paper was read by Mr. J. C. Elvy, A.M.I.E.E., on "Artificial lighting for cinematography." After giving a very interesting sketch of the evolution of the cinematograph, he described the system of illumination now in general use. So long as the photography was conducted in the open air it appears that no difficulties arose so far as the artistes were concerned; later, daylight was supplemented by powerful arc lamps. Nowadays most of the work is done in large enclosed studios in which appropriate scenery is set up. The work itself is done in a three-sided enclosure wider towards the camera than at the back. Masses of lights are arranged at the front on either side of the stage. These may be supplemented by overhead lights, or by lights concealed towards the rear of the stage. When "interiors" are involved light is made to stream through windows or doors from powerful arc lights which are nothing less than searchlights. The total effect is brilliant in the extreme, and this is required by the brevity of exposure necessary to secure a rapid stream of pictures for the film. The qualities aimed at in illuminants for these purposes are summarized as follows: High actinic value with relatively low consumption of energy and small losses in diffusion and reflection; low intrinsic brilliancy; absence of heat or fumes; constancy and steadiness of light. The author stated that "there seemed a general impression that the main source of eyesight trouble in the studios, when it occurs, is the exposure to sources of very great intrinsic brilliancy. It is possible that the strong ultra-violet component in some lights, which is highly desirable from the photographic standpoint, may accentuate a tendency to inflammation of the eyes. According to Dr. Chappé, the worst effects did not come on until two or three hours after leaving the studio, a symptom which would suggest ultra-violet irritation.

The influence of the cinematograph display upon the frequenters of the picture theatres was first considered by Mr. Bishop Harman in a paper dealing particularly with children, published four years ago in this Journal.¹ He ascribed the unpleasant effects of the display so far as they affected the eyes to the following conditions: 1, Glare; 2, flicker; 3, rapidity of motion; 4, concentration of attention; 5, duration of exhibition. He also showed that the effects were exaggerated when the observer was badly placed as regards the screen. He recommended that the best protection for the child would be secured by the following provisions: (1) The reasonable illumination of all parts of the hall not directly beside the screen; (2) the improvement of the movement of the film so as to reduce flicker, and the withdrawal of films immediately they are damaged; (3) an improvement in taking the picture so as to bring the rate of motion of the object depicted more nearly to the natural; (4) the increase in the number of intervals in the show; (5) the limitation of shows for children to one hour and the prohibition of repeats; (6) the reservation of the children's seats to the "optimum" position in the hall. With such provisions he did not think the indulgence in a show once a week should do harm to the eyes of a normal child. A little later, Dr. James Kerr contributed a paper dealing with some of the photometric problems of the display.²

In 1919 the London County Council requested the Society of Illuminating Engineers to appoint a committee to investigate the possible causes of eye-strain from cinema exhibitions. A joint committee of that Society with representatives of the Council of British Ophthalmologists, the Physiological Society, the cinema industry, and the London County Council was appointed. The committee issued an interim report in June, 1920.³

In that report the position of the spectator in relation to the screen is found to be of importance, bad position in a

vertical direction (from the screen being too high) being worst. A detailed formula is given for the limitation of these bad positions. Disturbing factors manifest themselves in flicker, due to jerkiness of movement of the pictures; and this is found to be more serious than the physiological flicker manifest to the eye by the keen light sense possessed by the periphery of the retina. Film defects were found to be annoying and were better eliminated, but the committee did not see its way to make recommendations thereon. The County Council had already required a standard illumination of halls whilst pictures are being shown; the committee thought that with improved methods this standard might be increased. The London County Council has now decided that in the case of any new cinematograph halls to be erected in London the recommendations of the Illuminating Engineering Society for preventing eye-strain shall be carried out, and shall also be made effective in existing premises as opportunity offers.

The following further subscriptions have been received from January 25th to February 5th, 1921, in response to the appeal published in the JOURNAL of July 24th, 1920 (p. 129), towards a presentation to Dr. J. A. Macdonald on the occasion of his retirement from the office of Chairman of Council of the British Medical Association which he had held for ten years. Subscriptions of any amount not exceeding five guineas should be made payable to "The Macdonald Presentation," and sent to the Medical Secretary, British Medical Association, 429, Strand, London, W.C.2.

AT a recent meeting of members of the North of England Branch of the British Medical Association held at Newcastle-on-Tyne, Dr. James Don, who served as Secretary of the Local Medical War Committee, was presented with a silver tea and coffee service together with a cheque; Dr. James Hudson, who for a time was Chairman of the Committee, received an eight-day chiming clock. The gifts were in acknowledgement of the services rendered to the profession by the recipients in arranging local medical services during the war. Dr. H. Rutter was presented with a gold watch and chain by the doctors on the panel in recognition of his services as secretary of the Panel Committee, and as their representative during the past few years. Subsequently the members present were entertained at supper by Drs. Don, Hudson, and Rutter.

STUDIES OF INFECTED WOUNDS.

In a special report to the Medical Research Council,* Captain S. R. Douglas, Mr. A. Fleming, and Dr. L. Colebrook describe a series of researches made by them on infected wounds of soldiers under treatment at St. Mary's Hospital during the great war. These studies were in close relation to those of Sir A. E. Wright, who had been actively investigating wound infections at No. 13 General Hospital, Boulogne, since an early stage of the war: the patients investigated at St. Mary's having been selected and forwarded from No. 13 General Hospital for that purpose.

This report is divided into three parts. Part I deals with the nature of the cases treated, the methods of treatment employed, and certain conclusions arrived at. Special forms of treatment are referred to, such as the method of skin grafting employed by Steele as long ago as 1870, now revived and modified apparently with great success. Another interesting observation is the effect of spraying a wound with certain aniline dyes such as malachite green or brilliant green in order to promote the growth of epithelium. A particularly successful and useful device employed by the present investigators was adopted by them for the purpose of alleviating the pain occasioned by dressing wounds. The principle, briefly, is to place next to the raw surface of the wound some freely perforated but non-absorbent material. Celluloid was at first employed, but later a still better material was evolved known as "perforated parax protective."

The second portion of the report is devoted to a description of the pathogenic bacteria found in the wounds and to a full account of the characters of these organisms. The point is made in the first place that in case of these war wounds the primary infection is made up largely of fascial bacteria. The micro-organism, however, of chief importance in war wounds is *Streptococcus pyogenes*, which "was present in practically every septic wound and was able to resist the bactericidal action of the body fluids and cells to a much greater degree than any of the other bacteria present. It was this coccus that was responsible for nearly every complication that occurred in the cases during their stay in the wards of the Inoculation Department, the commonest of these being erysipelas, the formation and persistence of sinuses, and also such constitutional symptoms as fever."

A study was made of the cultural and fermentative characters of 160 strains of streptococci present in 30 wounds taken at random. *S. pyogenes* was isolated on one occasion at least from 28 out of the 30 cases, and in 15 of them it was the only streptococcus found.

On analysis the 160 strains of streptococcus gave the following results: *S. pyogenes* 118 specimens, *S. salivarius* 10, *S. faecalis* 8, *S. equinus* 5, and *S. anginosus* 2; 17 of these streptococci were unclassified. A special interest attaches to the serological investigation which was made of specimens of *S. pyogenes*. First it was found that all of 24 strains of this streptococcus were agglutinated to approximately the same titre as the particular strain used in preparing the serum. Next it was demonstrated that the mannite-fermenting strain of *S. pyogenes* is of the same serological type as the ordinary strain of this coccus that does not ferment mannite. This identity of the strains of *S. pyogenes* occurring in wounds was established not only by agglutination, but also by absorption tests.

In addition to these studies of streptococci, specimens of diphtheroid bacilli, anaerobes, and *B. proteus* occurring in the wounds were carefully studied and their characters recorded. The frequency of diphtheroid bacilli in wounds is well known, and while the majority of them appear to be of minor significance, there is no doubt that occasionally a true Klebs-Loeffler bacillus is to be found. The present investigators suggest that some of the diphtheroid bacilli present in wounds may be specimens of the acne bacillus. Sixty-one strains of diphtheroid bacilli were investigated very fully and their characters defined. The vast majority of these strains were non-pathogenic to the guinea-pig; from four wounds, however, a bacillus was isolated that could not be distinguished from *B. diphtheriae* in pathogenic or other respects. The patients from whom these cultures of virulent diphtheria bacilli were isolated showed no clinical signs of such infection, no formation of membrane, and no constitutional disturbance. The work done on the anaerobic bacilli is a valuable supplement to that of the Anaerobic Committee, and the St. Mary's Hospital observers describe and name several new forms of these bacteria which they isolated from wounds.

The third part of this report contains a series of experimental studies of the interaction between the wounded tissues of the patient and the infecting bacteria in the presence of various antiseptics. It will hardly be disputed that the valuable and sustained researches of Wright and his colleagues at St. Mary's during the years that preceded the war, on the finer processes of immunity and phagocytosis, fitted them better, perhaps, than any other group of workers in Europe or elsewhere to undertake this particular line of war research. For this reason the present report of these investigators should be read, if possible, by all of those interested in the healing of septic wounds. That some progress has been made with regard to our understanding of the healing process is clear, but that anything approaching finality has yet been reached is open to doubt. Antiseptics of all the kinds investigated would appear to be of little or no value as such when tested *in vivo* by the methods described in the report. We could wish that at a future date the Medical Research Council would issue in a compact form an account of the completed work of Sir Almroth Wright and his colleagues on the biology of infected wounds. If to this volume there were to be prefixed a summary of the state of knowledge on this subject before the war began, it would be of great help both in raising appreciation of the ingenious and highly adaptable technique which is such an outstanding feature of the St. Mary's school, and also in facilitating assessment of the progress actually made towards solution of a problem of cardinal importance to the surgeon in peace as in war.

THE MILK SUPPLY.

If beer and other alcoholic beverages were produced under the same insanitary and unsavoury conditions as those which are associated with the production of a large quantity of the milk consumed in this country the task of those who are anxious to persuade the nation to "go dry" would be very much simplified. The reports of medical officers of health and other officials in pre-war days made us familiar with dark and unventilated cowsheds, the walls and floors of which were in a foul state, with fold-yards so choked with manure that the cows had to plunge through it in order to enter the sheds to be milked, their udders trailing in the filth, and we were told of dairy farms with inadequate water supplies, resulting in uncleanly utensils and unwashed hands of milkers.

The vigorous propaganda that has been carried on for the last ten or fifteen years has left the dairy farmer no excuse for continuing his lax practices. It has had a considerable effect on the more public spirited owners and farmers; scattered up and down the country to-day are many dairy farms which may at least serve as models. Nevertheless, the position generally is that stated by Lieut.-Colonel Brittlebank, of the Public Health Department of the Manchester Corporation, in his report to Dr. James Niven, the medical officer of health, for 1919: "My impression," he says, "on visiting some of the country farms was that, so far as cleanliness was concerned, we were very much in the same position as we were fifteen years ago. The cowsheds were dirty and the cows were in a general state of filth." For years past public health reformers have been crying out for amendments in obvious directions, but to very little purpose, though in April last the Ministry of Agriculture and Fisheries was constrained to issue a Memorandum in which it was stated that there was an abundance of evidence in support of the contention that the milk supply on reaching the large consuming centres was too highly charged with dirt and bacterial life.

The trade of a dairyman and cowkeeper is regulated by the Dairies, Cowsheds, and Milkshops Order, 1885, and the amending Orders of 1886 and 1899, and Regulations which may be made under the provisions of those Orders. The authorities charged with their administration are the urban and rural district councils, the members of which, as regards the rural councils, are largely drawn from the dairy farmers themselves, so that it can hardly be expected they should display much enthusiasm in enforcing regulations which necessitate any very considerable outlay. Indeed, many rural authorities refuse even to make regulations, and the supervision carried out is either absent or wholly inadequate.

It is a strange commentary upon the manner in which our great central departments are conducted that whereas the Ministry of Health and the Ministry of Agriculture and Fisheries appear to have failed in effecting reforms there should have come to their assistance a subcommittee appointed under Profiteering Acts. In January of 1920 this subcommittee was deputed to "investigate the question of trusts, combines, agreements, and other conditions affecting prices in connexion with the milk trade, including milk products so far as they relate to the consumer in this country." This Committee has just reported, and it is satisfactory to find it stating that recent large combinations of milk distributors have not dealt unfairly with either the producer or consumer and that large economies have been effected by the combinations. The most important conclusion,

however, is "that there is still ample room for improvement in the methods of dealing with milk at all stages, both from an economical point of view and also having regard to the health of the nation. We recommend that all milk should be delivered in bottles. In order that this may be accomplished, we consider that either some form of combination amongst the distributors is inevitable, or municipalities should be empowered to undertake the distribution."

Hitherto attempts at municipalizing milk supplies have not met with success. Whether such an enterprise would tend to lower the price of the commodity is more than doubtful, but it might be expected that the conditions of production would be improved as compared with the general farming standard as it exists to-day. The unsatisfactory administration of the laws regulating the supply of milk generally applies with equal force when the question of the distribution of milk from tuberculous cattle is considered. The Dairies, Cowsheds, and Milkshops Orders, which are operative throughout England and Wales, prohibit the sale or use for human food of milk from a cow which is certified by a veterinary surgeon to be suffering from tuberculous disease of the udder. What have come to be known as the Manchester Milk Clauses because they were contained in the Manchester General Powers Act, 1899, have been incorporated in several other private Acts—for example, in the Liverpool Corporation Act, 1900. These clauses prohibit, under a penalty, the sale of milk from a cow known to be suffering from tuberculosis of the udder. They also enable supplies of milk to be followed up to the dairy farm itself wherever it may be situated, and gives power, if found necessary, to prohibit the supply of milk from the farm. In Manchester during 1919, in 20 out of 351 samples of mixed milk examined tubercle bacilli were found. During the consequent visits of inspection 13 cows were definitely proved by bacteriological examination to be suffering from tuberculosis of the udder. Ten of these cows were slaughtered under direct supervision, and in all cases the carcasses were found to be unfit for human consumption and were condemned.

CREMATION IN ENGLAND.

Among the enlightened classes opinion is steadily growing in favour of cremation; but among the community at large sentiment and prejudice still stand in the way of a general resort to this means of disposal of the dead. It is possible, however, that the acute shortage of land accommodation—for the dead as well as for the living—in the neighbourhood of all populous centres may bring the claims of cremation into greater prominence, and so induce public authorities to increase the facilities. It might happen that with a larger number of crematoria in various parts of the kingdom demand would keep pace with supply, for the cost of transporting a body by rail is at present prohibitive to persons of ordinary means, and this is a factor favouring earth burial, at any rate in country districts. Extracts sent us in advance from the report of the Cremation Society of England indicate that during the past year some 1,800 cremations were carried out in this country, and of these nearly one-half took place at Golders Green. In no instance, it is stated, was there any reason to doubt the cause or the fact of death, so efficient is the working of the precautions laid down by the Act passed by Parliament for this purpose. For nearly half a century the Cremation Society has carried on its valuable work. It has striven to overcome opposition and prejudice by practically demonstrating its objects, unaided by the State, and imposing no burden upon local rates, but mainly

DANGEROUS DRUGS REGULATIONS.

PROTEST BY THE BRITISH MEDICAL ASSOCIATION.

THE following letter and memorandum were addressed on February 3rd to the Home Secretary by the British Medical Association.

429 Strand, W.C.

Sir,

I have the honour to forward the enclosed memorandum concerning the draft Regulations made by the Secretary of State under Section 7 of the Dangerous Drugs Act of 1920.

The Association wishes to impress on you, Sir, that the medical profession is seriously alarmed at the prospect which the proposed operation of the Regulations opens up. The responsibilities and anxieties of medical practitioners—already great—seem likely to be seriously increased by clerical work and restrictions of a kind hitherto unknown in medical practice.

The Association trusts that you will withdraw the Regulations pending consideration of the question *de novo* in conference with representatives of the medical, dental, veterinary, and pharmaceutical professions; or, failing that, that you will allow this Association to state its objections to the Regulations by a small deputation.

Yours obediently,

ALFRED COX,

Medical Secretary

The Secretary of State for Home Affairs,
Home Office, Whitehall.

MEMORANDUM

SUBMITTED BY THE BRITISH MEDICAL ASSOCIATION TO THE SECRETARY OF STATE FOR HOME AFFAIRS CONCERNING DRAFT REGULATIONS MADE BY THE SECRETARY OF STATE UNDER SECTION 7 OF THE DANGEROUS DRUGS ACT, 1920 (10 and 11 Geo. 5, Ch. 46).

1 The British Medical Association is well aware of the public danger arising from the improper use of the drugs whose manufacture, sale, possession and distribution it is proposed to control under these Regulations, and has on several occasions urged the necessity of such control. It further recognizes that in consequence medical practitioners must submit to the imposition of certain restraints in prescribing, compounding, dispensing and of certain clerical duties in them.

2 But it appears to the Association that the Regulations as drafted will have effects far beyond those contemplated in Section 7 of the Dangerous Drugs Act of 1920, under which they are made and which states expressly that they

are to be "for the purpose of preventing the improper use of the drugs to which this part of the Act applies."

3. On the one hand, the medical profession will be hampered in its legitimate use of these drugs in treating the sick, and on the other hand the public will be inconvenienced by delay in obtaining medicines necessary for their treatment, and may even in some circumstances be deprived of remedies which, properly used, are invaluable in the relief of pain and in the saving of life. The cost of medicines containing these drugs must also be seriously increased if the restrictions contained in the Regulations are enforced.

4. As it is understood that it is necessary for the Regulations to be brought into force at an early date owing to the probable early lapse of the powers under the Defence of the Realm Regulation 40 B, some detailed criticisms of the draft Regulations in so far as they affect medical practitioners are herewith submitted. These criticisms must not, however, be regarded as complete.

5. The Association regrets that, so far as it is aware, no opportunity was afforded to any body representing the medical profession, or any other of the professions concerned, to give advice on the practical side of the question before the opinions of the Home Office were crystallized into draft Regulations. The Association knows by long experience how much easier it is to influence such regulations while they are in a fluid state and before they have been made public.

Regulation 5.

"Prescription must be in writing."

(a) Some medical men typewrite their prescriptions. It is difficult to see that this favours any improper use of the drugs, provided that the other provisions as to date, address, signature, and qualifications are carried out.

(b) Prescriptions, particularly in hospital work, may be printed—for example, where a stock mixture is ordered and to this a scheduled drug may be added.

"And marked with the words 'Not to be repeated'."

This appears to be totally unnecessary as it is fully provided for by Regulation 6 (a) and (b).

"A prescription for the use of the drug, must be given by a duly qualified medical practitioner, and must comply, etc."

This appears to forbid every personal administration of the drugs by a duly qualified medical practitioner, or under his direct personal supervision, unless he writes a prescription in each case. In hospital practice particularly this would be impracticable (See below).

Regulation 6.

This Regulation should not apply to a medical practitioner dispensing his own medicines. It is customary to enter all prescriptions in a day book, showing the name and address of the patient to whom supplied and the date on which supplied.

If this Regulation be enforced it appears that it will be necessary to keep four records of each transaction:

1. The customary record in the day-book of the service given to the patient and all medicines supplied, including, perhaps, things additional to the scheduled drug.
2. The prescription for the scheduled drug under Regulation 6 (b).
3. The record of the ingredients of the prescription, etc., in a special book under Regulation 6 (c).
4. The record in a special book for the special drug under Regulation 9 (b) and (c).

Regulation 8.

As drafted, the Regulation seems to demand that every mixture containing any of the scheduled drugs or preparations, even though the percentage may be below that laid down in Regulation 1, must have plainly marked on it the amount of the drug contained. This is probably not intended, as it would bring in such medicines as ordinary cough mixtures and the like, which appear to be expressly excluded from the operation of the Dangerous Drugs Act.

In any case the Regulation should not be applied to articles dispensed in pursuance of a prescription given by a duly qualified medical practitioner or to articles dispensed by a duly qualified medical practitioner for the personal use of his own patient, for two reasons:

1. Nervous and apprehensive patients would hesitate or even refuse to take or use medicines so labelled.
2. All patients taking or using these drugs on their doctor's prescription would become aware of the fact and also of the exact nature and dose of the drug prescribed. The objections to this are obvious and have been recognized in the nomenclature of the British Pharmacopoeia in the case of at least some preparations. The fact that they contain this drug by the name of some inert component—for example, opium pill is called *pilula saponis composita*, and opium suppositories are called *suppositoria plumbi composita*.

This Regulation will, in fact, not carry out the "purpose of preventing the improper use of the drugs to which this part of this Act applies," to quote Section 7 of the Dangerous Drugs Act, but will have exactly the contrary effect.

Regulation 9.

As applied to medical practitioners these records appear to be unnecessarily complicated.

- (1) Clause (a): One book might be substituted for four books.
- (2) Clause (c): The entry of the drugs purchased or obtained on the day on which the drug is received is not always feasible. Drug hampers are not always unpacked on the day of receipt.
- (3) Clause (d): Separate books at each set of premises. This would involve a set of books at every branch surgery and at every practitioner's private house, apart from his main surgery, as it is necessary to keep a small supply of such things as opium pill, chlorodyne, and hypodermic tablets of morphine always ready for personal administration in case of emergency.
- (4) Clause (g): Information as to purchases, stocks, and transactions. This would involve a complete record of every use of any of these drugs, and would be quite impracticable to a busy practitioner. By far the largest amounts would be used in compounding mixtures whose strength is below that laid down in Regulation 1. There is also a considerable waste—for example, in giving hypodermic injections, throwing away old stock, and the like.

Regulation 13.

This Regulation would appear to interfere with the delivery of the drugs to persons licensed or authorized to possess them without their signed authority in writing. This would be troublesome in the case of railway and other carriers; very awkward where a doctor wanted a supply in emergency and wished to telephone to his chemist to send some at once instead of giving a written authority to a messenger and sending it by hand; and quite impossible in the case of a patient with a sudden attack of, for example, gall-stone colic, or with severe haemoptysis needing immediate treatment.

6. *Matters requiring to be Adequately Provided for in Draft Regulations.*—Personal administration of the scheduled drugs by a medical practitioner—for example:

- Instillation of cocaine into the eye in testing refractions or examining the eye, or in eye operations;
- Spraying the throat or nose with cocaine for purposes of examination or operation;
- Injecting cocaine as a local anaesthetic;
- Hypodermic injection of morphine or heroin;
- Administration of morphine suppositories.

It is not clear how these procedures are to be carried out under the Regulations. Must a prescription be written out in each case? Must a record be kept for each case as laid down in Regulation 6? In how far will it be legal to depute personal administration to nurses and to hospital orderlies?

In small hospitals without resident house-surgeons, in nursing homes, and in private practice where a trained nurse is in attendance, it is a common occurrence to leave a hypodermic injection or a sedative draught which would contain one of the scheduled drugs, to be given if neces-

sary. Would this be in conformity with the Regulations, or would the nurse or orderly be a person not authorized to be in possession of the drug?

7. The Association would urge the Secretary of State to defer the operation of the Draft Regulations until the representatives of the medical, dental, veterinary, and pharmaceutical professions have been consulted. If this is not granted, the Association would press upon the Secretary of State to receive a deputation which could place more fully before him the reasons which have convinced the Association that the Regulations are so impracticable that they are bound to be ignored or evaded on a very extensive scale.

Association Notices.

MEETING OF COUNCIL.

The next meeting of Council will be held on Wednesday, February 16th, in the Council Room, 429, Strand, London, W.C.2, at 10 a.m.

MOTIONS FOR ANNUAL REPRESENTATIVE MEETING, NEWCASTLE, JULY, 1921.

NOTICES OF MOTION by Divisions, Constituencies, or Branches, for the consideration of the Annual Representative Meeting of the Association, commencing Friday, July 15th, 1921, proposing to make any addition to or any amendment, alteration, or repeal of any Article or By-law, or to make any new Article or By-law, or proposing material alteration of the policy of the Association in matters relating to the honour and interests of the profession or of the Association, must be published in the BRITISH MEDICAL JOURNAL SUPPLEMENT not later than May 14th, and for this purpose should be received by the Medical Secretary not later than April 30th.

BRANCH AND DIVISION MEETINGS TO BE HELD.

METROPOLITAN COUNTIES BRANCH: CAMBERWELL DIVISION.—A meeting of the Camberwell Division will be held on Wednesday, March 2nd, when Dr. H. C. Cameron, of Guy's Hospital, will give an address on Children.

METROPOLITAN COUNTIES BRANCH: WILLESDEX DIVISION.—A meeting of members and non-members will be held on Tuesday, February 15th, at 8.30 p.m., at St. Andrew's Parish Hall (Institute behind Church), High Road, Willesden Green, N.W. The meeting will consider proposals made by the Medical Officer of Health of Willesden, at the request of the Committee, for staffing the clinics with part-time medical practitioners. Dr. Anderson, Deputy Medical Secretary, has been instructed by the Council of the British Medical Association to advise and assist the Division in preparing a scheme for working clinics, and will be present.

SUSSEX BRANCH: CHICHESTER AND WORTHING DIVISION.—A meeting of the Division will be held at the Steyne Hotel, Worthing, on Wednesday, February 16th, at 6.30 p.m. Dr. A. F. Hurst, Physician and Neurologist to Guy's Hospital, will give an address on Asthma. Members wishing to stay for dinner (price 7s. 6d.) are requested to notify Dr. H. Milbank-Smith, Worthing Lodge, Worthing, by Monday, February 14th.

Meetings of Branches and Divisions.

METROPOLITAN COUNTIES BRANCH: CITY DIVISION.—A MEETING of this Division was held on January 27th at the Metropolitan Hospital. Dr. E. W. GOODALL delivered an address on the "Nervous group of the acute infectious fevers." The members were very interested in the lecture, which was comprehensive and exceedingly useful from a practical point of view. A hearty vote of thanks was accorded to Dr. Goodall for his kindness in delivering the lecture.

SOUTHERN BRANCH: PORTSMOUTH DIVISION.

Dangerous Drugs Regulations.
At a meeting of the Executive Committee, Portsmouth Division, held on February 3rd, the following resolution was unanimously adopted:

We, the members of the Executive of the Portsmouth Division of the British Medical Association, having read the proposed regulations for the sale of dangerous drugs etc., emphatically protest against their application to us to carry them out: the result will be bound to ignore the regulations or his patients will be supplied with valuable and anodyne drugs, and thereby their suffering will go unrelieved.

It was also resolved that copies of this resolution be sent to the Home Secretary, to local members of Parliament, and to the medical press.

INSURANCE. CORRESPONDENCE.

The New System of Medical Records.

SIR,—The Insurance Acts Committee of the British Medical Association is issuing a memorandum on the character of the new system of medical records, which will be found to be more or less a defence in favour of their acceptance by the panel practitioner.

I believe the memorandum is divided into three parts, the first being a history of what has led up to the institution of the records, and the remaining parts will be mainly a critical defence of their favourable reception.

As to the first part, which concerns history, I have very little to say. It seems to me to be a correct and fair statement. As a matter of fact, this system was laid before the last Panel Conference held in London, and duly accepted by that conference for trial. I was not present at that conference, and do not feel justified in agreeing with the decisions of the conference. I am under the impression that the full nature of the new system was hardly comprehended by the delegates when they determined to give it a trial. Previous conferences have passed some very definite lines of liberty which should characterize any new form of records to be introduced. For instance, it was determined by a special conference in July, 1919, that the "Commissioners be requested to devise some simpler form in order to make work less onerous"; and again at the same conference, "that whilst not objecting to the principle of records in a simple form, the conference strongly opposed any complex system involving a multiplicity of forms with a consequent increase in clerical work."

I am under the impression that the last conference, which accepted the present record system, hardly comprehended the complexity of the system, accompanied as it is with multiplicity of forms and consequent increase in clerical work. However, they resolved that the new system should be given a trial, and the Insurance Acts Committee was perfectly justified in taking the view that it was their duty to smooth the way, so far as possible, for a fair trial to be given to the new system.

The trial is now in operation, and there are very varied accounts from different parts of the country as to their being received with favour or disfavour. I am told that in Lancashire there is an opinion favourable to the new system, a statement which surprises me considerably, for my own county entertains a very strong feeling of antagonism towards the system, which they consider alike complex, accompanied with an undue multiplicity of forms and burdensome pressure of increased clerical work. It seems to me, therefore, that it is opportune from the commencement to discuss the working of this system in its trial in the initial stages, and I think there should be ample opportunity given for the expression of the views of panel practitioners upon the bearing which this system has on their professional life. I am bound to admit that we have, more or less, deserved what we have got, but I do not think we should, any of us, be deterred from the expression of our opinions of the system now that it has come.

If the system is to remain, the wisdom of which I gravely doubt, it should, to my mind, be made less burdensome to the practitioner, and much less inquisitorial into the ailments of insured persons. If any records of ailments are to be made it seems to me they should only be those of a serious, acute, or preventable character, in which there may be shown to be some local circumstances, in the districts where insured persons dwell, which may require the more efficient oversight of sanitary authorities.

It is said that there is no obligation to enter notes in these records of every trivial illness or symptom. I do not so read the Regulations, for I think the intimation is quite clear that all ailments of every kind are to be entered in the records, and we must take the thing for what it is, and not what it ought to be, if we are to estimate its true value. An entry is certainly to be made in the column headed "Diagnosis" "when a definite and reasonably certain conclusion" has been arrived at. Thus if a married or unmarried woman has a miscarriage it must be entered as such. A spade must be called a spade, and not an excusable or inexcusable shovel.

The entry of all consultations and visits is required. If that means anything, it must imply what the word states, and every single consultation should find its place in the record. To my mind, also, it is necessary to enter every certificate that is given, though there seems a desire to prune down the record of the number of certificates. Whatever we may desire in this respect, I gather from the Regulations that all consultations and certificates must be

entered, and not simply the first and the final certificates. In other words, all intermediate certificates should, in my judgement, according to the said Regulations, find their due entry. If there is to be any alteration of detail, the sooner pronouncement is made on that matter the better, because there is a great diversity of opinion as to the extent of the obligation of the entries which will have to be made in the records.

I am unable, also, to sympathize with the protest against the comment in what is called the "Political Press." Doubtless every opportunity is taken for every act of a departmental official of the Government to be brought within the range of adverse criticism if the policy of the paper so dictates, but surely we have nothing to do with that. The protest of panel practitioners if they object to this system is not a political protest against the Government, but a professional and personal objection to the incidence of the burden which departmental officials are placing upon panel practitioners. Whether the Press approves or disapproves is a matter entirely for them, and we should be surely justified in making use of any portion of the public press which voices the sentiment of the profession for the time being. In this matter we have nothing to do with political quarrels. We are taking a purely business and not political view of this matter, and I hope we shall endeavour to keep outside the sphere of the party political game. Whatever it may be, we should have no part or lot in that sort of thing.

A good deal has been said in some papers by way of protest against the infringement of secrecy, which has hitherto prevailed between the medical practitioner and his patient in the matter of the privacy of the professional consultation which has taken place between them, and it has been said that too much has been made of this charge of violation of secrecy. To my mind, it is impossible to say too much about anything, whether it is legislative or departmental administration, which interferes with the privacy of a citizen's ailments. The State has no business to exercise an inquisitorial investigation into matters of private concern. If the individual is suffering from a preventable disease of an infectious or contagious character, then it becomes a matter not of private but of public interest, and legislation has very properly dealt with that matter; but the poor and the rich are all treated alike in that respect. The peer of the realm or the pauper in any parish are equally notifiable if they suffer from infectious diseases, but beyond that the general practitioner finds an alteration of the treatment of the individual, according to whether he may or may not be an insured person.

Departmental administration says that it will acknowledge no private right of the individual in this respect. There, it seems to me, a grave departure in the equality of the treatment of individuals has taken place. Why should certain people who are better off, so as to be outside the insurance scheme, be treated more favourably than those who are obliged, perforce by economic circumstances, to be numbered as insured persons, to be ticketed and labelled with all their ailments, in the same way as paupers have always been treated under the Poor Law system? It is the introduction of that antiquated system in a new form, and to my mind is highly objectionable. After all, illness is no respecter of persons. Kipling has put the solid truth in this matter when he said:

"For the Colonel's lady and Judy O'Grady
Are sisters under the skin."

Why should the colonel's lady be exempt from finding a place on the ailments schedules of Government departments while her poorer sister, Judy O'Grady, is duly labelled, ticketed, and docketed? That is exactly what has happened. One can readily see how this sentiment finds its reflection in a great deal of uneasiness which is being felt by insured persons, and, I think, not without reason. No Government department has any right to treat Mary Ann differently than it will treat her mistress the Lady Jane. The Lady Jane is exempt from interference, but her maid, Mary Ann, must go on the schedules. Lady Jane may be a far more dangerous person than Mary Ann, but Government authorities would not dare to bring her within the schedules of ordinary ailments.

There is another matter which I think to the panel practitioner is of grave moment. We have been frequently told, when discussions have taken place on the subject, that it was never intended that the panel practitioner should be subject to any regular inspection in his work. Panel conferences have protested against it, and we have always been assured that no system of inspection would ever take place, but now it appears that these district officers, regional or otherwise, "or such other persons as they may appoint for the purpose," forsooth, are to have access

at all reasonable times to these records, and we are to furnish them with any necessary information with regard to the entries therein which they may require. This is a gross betrayal, and, if we are to submit to it, will be a surrender of all the present liberty in the exercise of our professional duties which hitherto we have always enjoyed. We are to be inspected, forsooth, at every turn in all our panel work. To my mind this is State inspection with a vengeance, and the commencement of what will be infinitely worse in detail as time goes on, unless we can destroy the obnoxious innovation. We said we would not, we have always said we would not, and I hope we shall say we will not submit to this system of inspection.

This system was to have a trial. The trial is with us now. We have put the shoes on, and we have a right to say where they pinch.

I hope that some of the most objectionable features of this record system will soon be revised and altogether withdrawn. It is quite possible to devise a simple system which would be useful and helpful as between practitioner and practitioner in the interests of patients, but it would not be this system of medical records.—I am, etc.,

Crewe, Feb. 6th.

WILLIAM HODGSON.

Dr. G. YOUNG EALES (Torquay) writes: "In the SUPPLEMENT of February 5th, page 34, A. B. C. asks where he can purchase the Dextro filing case for insurance record envelopes. The address is Dextro, Ltd., 30, Arcade Chambers, St. Mary's Gate, Manchester. The case is cheap, handy, and convenient."

Several other correspondents have been good enough to send this information.

Naval and Military Appointments.

ROYAL NAVAL MEDICAL SERVICE.

The following appointments are announced by the Admiralty: Surgeon Commanders J. H. Lightfoot to the *Conqueror*, J. Boyan to the *Defiance*, C. T. Baxter to the *President*, additional, for R.N. Recruiting Headquarters. Surgeon Lieut. Commander F. C. Wright to the *Birmingham*. Surgeon Lieutenants F. L. H. McDowell to Haulbowline Hospital and Dockyard, J. C. Brown to Special R.M. Battalion, H. B. Parker, D.Sc., to the *Undaunted* for voyage.

ARMY MEDICAL SERVICE.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Colonel A. E. Master retires on retired pay.
Lieut.-Colonel J. D. G. Macpherson is placed on retired pay on account of ill health contracted on active service.

DIARY OF SOCIETIES AND LECTURES.

- HARVEIAN SOCIETY**, Town Hall, Harrow Road, Paddington.—Thurs., 8.30 p.m., Dr. Wm. Brown: Psycho-analysis.
- HUNTERIAN SOCIETY**, Sion College, The Embankment, E.C.—Wed., 9 p.m., Oration by Dr. H. H. Bashford: The Ideal Element in Medicine.
- MEDICO-LEGAL SOCIETY**, 11, Chandos Street, W.1.—Tues., 8.30 p.m., Dr. Halliday Sutherland: Medical Evidence in the Staunton Murder Trial.
- MEDICAL SOCIETY OF LONDON**, 11, Chandos Street, W.1.—Mon., 8.30 p.m., Discussion on Skin Disease: Its Relation to Internal Disorder, to be introduced by Sir James Galloway, followed by Dr. Arthur Hall, Dr. E. W. Goodall, Dr. A. Whitfield, Dr. E. Graham Little, Dr. H. W. Barber, Dr. H. G. Adamson, Dr. J. M. H. MacLeod, Dr. H. MacCormac, and Dr. R. Hutchison.
- ROYAL COLLEGE OF PHYSICIANS**, Pall Mall East, S.W.—Thurs., 5 p.m., Dr. Martin Flack: Milroy Lecture—Respiratory Efficiency in Relation to Health and Disease.
- ROYAL COLLEGE OF SURGEONS**, Lincoln's Inn Fields, W.C.—Mon., 4 p.m., Hunterian Oration by Sir Charters J. Symonds, K.B.E., C.B.; Wed., 5 p.m., Arris and Gale Lecture by Dr. F. W. Edridge-Green, C.B.E.: Cause and Prevention of Myopia.
- ROYAL SOCIETY OF MEDICINE**.—General meeting of Fellows, Tues., 5 p.m. *War Section*: Mon., 5 p.m., Exhibition and Demonstration of Splints etc., by Major M. Sinclair; 9 p.m., Paper with illustrative slides by Major Sinclair. *Section of Therapeutics and Pharmacology*: Tues., 4.30 p.m., Dr. J. H. POST-GRADUATE COURSES AND LECTURES.

- GLASGOW POST-GRADUATE MEDICAL ASSOCIATION**, Royal Hospital for Sick Children.—Wed., 4.15 p.m., Mr. A. MacLennan and Mr. W. Rankin: Surgical Cases.
- HOSPITAL FOR SICK CHILDREN**, Great Ormond Street, W.C.1.—Thurs., 4 p.m., Dr. Cockayne: Myopathy.
- LONDON LOCK HOSPITALS**.—Clinical Instruction daily. Lectures (Male Hospital, Dean Street, W.1.) Mon., 5 p.m., Mr. Gibbs: Ante-

- natal and Post natal Treatment of Syphilis; Tues., 2.30 p.m., Mr. McDonagh: Laboratory Results and Clinical Experience; Wed., 4.30 p.m., Mr. Joly: Tests of Cure for Gonorrhoea; Fri., 4 p.m., Mr. Abraham: Early Syphilitic Rash.
- MANCHESTER BABIES' HOSPITAL**.—Sat. 3.30 p.m., Dr. Renshaw: Congenital Syphilis.
- MANCHESTER ROYAL INFIRMARY**.—Tues., 4.30 p.m., Dr. F. E. Tylecote: Lumbar Puncture and Its Value in Diagnosis.
- NATIONAL HOSPITAL FOR DISEASES OF THE HEART**, Westmoreland Street, W.1.—Mon., 5.30 p.m., Dr. Russell Wells: Irregular Heart Action.
- NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC**, Queen Square, W.C.1.—Daily, excepting Wed. and Sat., 2 p.m., Out-patient Clinics. Lectures.—3.30 p.m., Mon., Dr. K. Wilson: Old and New Aspects of Syphilis; Tues., 3.30 p.m., Dr. Collier: Acute Poliomyelitis; Thurs., 3.30 p.m., Thurs., Dr. Taylor; Fri., Dr. Booth.
- NORTH-EAST LONDON POST-GRADUATE COLLEGE**, Prince of Wales's General Hospital, Tottenham, N.15.—Daily, 2 p.m., In- and Out-patient Clinics, Operations, etc. Lecture Demonstrations:—Mon., 4.30 p.m., Mr. Tanner: Surgical Cases; Tues., 4.30 p.m., Dr. A. J. Whiting: Innocent Irregularities of the Heart; Wed., 3 p.m., Dr. Oliver: Skin Cases; Thurs., 3 p.m., Mr. Carson: Surgical Cases; Fri., 3 p.m., Mr. Benians: Diagnostic Clinical Pathology.
- NORTH OF ENGLAND BRANCH, British Medical Association**, Royal Victoria Infirmary, Newcastle-upon-Tyne.—Fri., 2.15 p.m., Mr. Grey Turner: Cancer of the Colon; 2.45 p.m., Dr. D. W. Patterson, O.B.E.: Diseases of the Bronchi; 3.15 p.m., Professor H. B. Angus: Splint Treatment of Fractures of the Upper Extremity; 3.45 p.m., Tea; 4 p.m., Dr. A. F. B. Shaw: Arterial Degeneration; 4.30 p.m., Mr. N. Hodgson: Compound Fractures.
- SALFORD ROYAL HOSPITAL**.—Thurs., 4.30 p.m., Mr. Smalley: Nasal Sinusitis.
- ST. MART'S HOSPITALS**, Manchester, Whitworth Street West Branch.—Fri., 4.30 p.m., Mr. Morley: Acute Intestinal Obstruction in Infants.
- WEST LONDON POST-GRADUATE COLLEGE**, Hammersmith, W.—Daily, 10 a.m., Ward visits; 2 p.m., In- and Out-patient Clinics and Operations. Lectures.—5 p.m., Mon., Mr. Harman: Intestinal Sepsis and Irido-cyclitis; Tues., Dr. Morton: X-ray Appearances of Stomach Diseases; Wed., Dr. Owen: Gastric Disorders; Thurs., Dr. Bruce: X-ray Diagnosis of Joint Disease; Fri., Mr. Baldwin: Appendicitis.

British Medical Association.

OFFICES AND LIBRARY, 429, STRAND, LONDON, W.C.9.

Reference and Lending Library.

THE READING ROOM, in which books of reference, periodicals, and standard works can be consulted, is open to members from 10 a.m. to 6.30 p.m., Saturdays 10 to 2.

LENDING LIBRARY: Members are entitled to borrow books, including current medical works; they will be forwarded, if desired, on application to the Librarian, accompanied by 1s. for each volume for postage and packing.

Departments.

Diary of the Association.

FEBRUARY.

- 15 Tues. London: Scrutiny Subcommittee, 2 p.m.
Wilkesden Division, St. Andrew's Parish Hall, High Road, 3.30 p.m.
- 16 Wed. Croydon: Division, Steyne Hotel, Worthing, 6.30 p.m.; address by Dr. A. F. Hurst on Asthma, 6.45 p.m.
- 24 Thurs. London: Dominions Committee, 3 p.m.

APPOINTMENTS.

- GRIFFITH, Nora, B.A., M.B., B.Ch., B.A.O. Dub., Assistant Medical Officer of Health and School Medical Officer to Mountain Ash Education Committee, Glam.
- MORLEY, John, Ch.M., F.R.C.S., Honorary Assistant Surgeon, Manchester Royal Infirmary.
- STUART, F. J., O.B.E., M.R.C.S., L.R.C.P., Medical Superintendent, County Mental Hospital, Berry Wood, Northampton.

BIRTHS, MARRIAGES, AND DEATHS.

The charge for inserting announcements of Births, Marriages, and Deaths is 9s., which sum should be forwarded with the notice not later than the first post on Tuesday morning, in order to ensure insertion in the current issue.

BIRTHS.

- DICK.—On February 6th, at Beaufort House, Grange Park, Ealing, the wife of Major A. M. Dick, F.R.C.S., I.M.S., a daughter.
- EAGER.—On February 6th, at Exminster, Devon, the wife of Richard Eager, O.B.E., M.D., of a son.

DEATHS.

- HASSALL.—On January 31st, at The Dingle, Manor Road, Worthing, John Hassall, M.D., M.R.C.S., F.R.N.S., late of Northwick, Cheshire and Headingley House, Knutsford, aged 65 years.
- SCOTT.—At "The Tower," Murrayfield, Edinburgh, on February 2nd, Sarah Jeffrey, wife of Dr. Joseph Scott, Teheran, Persia.

from funds provided in the first instance by a few public spirited supporters. Since the opening of the Woking crematorium in 1885 nearly 23,500 bodies have been cremated in Great Britain. In addition to the crematoria at Golders Green, Woking and Norwood, there are others in Manchester, Glasgow, Birmingham, Liverpool, Sheffield, Leicester, Hull, Leeds, Bradford, Ilford and Darlington. The Cremation Society has this year inaugurated a scheme of free registration, enabling those who prefer cremation to record during lifetime their wish for this method of disposal at death. Information may be obtained from the Secretary, 52, New Cavendish Street, W. By enlisting the co-operation of a wider circle of living adherents the Society hopes to secure in time the abolition of earth burial, with its danger to health and its waste of money, labour and land. In the United States progress has been more satisfactory. According to the new *Hazell Annual and Almanack* there were in 1919 in the United States 79 crematoria. In that year 12,372 bodies were cremated, which was more than in 1916 but very much less than in 1918, when for some reason all previous records were far surpassed.

VITAMINES.

THE current number of the *Biochemical Journal* contains a number of papers dealing with conditions which determine the presence of vitamins and bring about their diminution or destruction in the course of the preparation of food for the table. Professor Gowland Hopkins points out that a knowledge of the conditions affecting the stability of vitamins is not only of practical importance in connexion with the commercial and domestic treatment of food, but would also be of value in guiding attempts to isolate them, and in limiting hypotheses as to their nature. Many investigations made during recent years of the fat-soluble A vitamins have shown that animal fats, with the exception of lard, are decidedly richer in it than vegetable oils. Conflicting statements have been made as to the resistance of this vitamin to heat. Some experimenters have concluded that it is thus readily destroyed, but in his paper opening the discussion in the Section of Medicine at the annual meeting at Cambridge, Professor Hopkins confirmed the statement of Osborne and Mendel that it is resistant to heat. The explanation of the difference of opinion, he states, is that while the vitamin in butter is not diminished by exposure to a temperature of 120° C. for four hours, it is within the same period greatly diminished and in twelve hours altogether destroyed if the butter is thoroughly aerated during the heating. Drummond and Coward now give an account of an experiment which led them to the same conclusion. The probability is that the destruction of the vitamin is due to oxidation, and this appears to be confirmed by Hopkins's observation that vitamin A disappears from butter spread in thin layers and exposed to air at temperatures of 15° to 25° C.; Drummond and Coward found that the loss was considerable at 37° C. Lard, as has been said, has been looked upon as an exception to the rule that animal fats contain vitamin A. This seems to be due not to the complete absence of vitamin from the body fat in pigs, but to two circumstances—first, that the diet usually employed to fatten pigs is not rich in vitamin A, and, secondly, that in the process of manufacturing lard, which involves raising the fat to a temperature of 102° C., much of any vitamin A there may be must be destroyed. Drummond, Golding, Silva, and Coward relate an instructive experiment made on a litter of Berkshire pigs. For the present purpose it will be sufficient to say that it demonstrated storage of vitamin A in the body fat of pigs receiving a diet containing considerable amounts of vitamin A, yielded, in this instance, by fresh grass. The fat of the pig, probably because the animal fattens quickly, contains less vitamin A than that of other animals, and when a young pig is fed

on a diet very deficient in vitamin A, such as toppings and whey, it may not be possible to detect that vitamin in the body fat. An interesting point as to the value of milk in maintaining growth is discussed in another article by Professor Hopkins; in one of his earlier papers on accessory food factors (1912) he had described the startlingly favourable effect of adding minute amounts of milk to synthetic diets incapable by themselves of maintaining the growth of rats. Experiments made later by Drummond and by Osborne and Mendel failed to yield the same results, and those made by Hopkins himself in the winter of 1919 were disappointing, for though the animals who received the small quantity of milk kept in better health and lived longer than those on a synthetic diet alone, they grew very slowly and their death rate was high. In another set of experiments which he began in April and May the contrast between animals receiving the small quantities of milk and the others who received none was as marked as in his earlier experiments. The difference in the diet of cows in summer and winter suggests itself as a probable explanation, and McCarrison has in our columns laid stress on this point. Osborne and Mendel, however, were unable to show that this factor influenced their results, and an experiment Professor Hopkins made with goats gave no support to the theory. There is seasonal variation in the growth of energy of rats, but Professor Hopkins doubts whether this would account for the experimental difference, and regards the question as still open.

HOME SERVICE AMBULANCES.

THE Home Service Ambulance Committee of the Joint Council of the British Red Cross Society and the Order of St. John has prepared a report of its work down to the end of last year. The object with which it was formed, shortly after the Armistice, was to establish a motor ambulance service in England, Wales, and Ireland, which would afford means for rapidly and easily conveying the sick and disabled, especially those in rural areas, to a hospital or other institution for treatment. Ambulances which had been in use in France during the war were overhauled and the most suitable put into a state of repair. In April, 1919, a circular letter was addressed to county directors inviting them to apply for such number of motor ambulances on loan as would meet the needs of the county, the suggestion being that the ambulance garages should be approximately thirty miles apart, so that there would always be one not more than fifteen miles from a patient. The distribution of ambulances began on May 24th, 1919, and by the end of that year 238 had been stationed; by the end of last year the number had been increased to 273. During the first twelve months of the Committee's work the total number of cases carried in the ambulances was only 5,227; three months later this was increased to 22,409, and at the end of 1920 the total number carried had risen to 38,260. Poor Law cases are conveyed at the cost of the local authority, but there are many patients whose circumstances are such that the charge for the use of the ambulance must be partly or entirely remitted. Nevertheless, in many counties the receipts have been sufficient to cover the cost of the service. The home ambulance service has become an established institution. The military ambulances originally issued are being replaced by a lighter type. The light ambulances have room for two stretchers only instead of four, but in practice this has not been found disadvantageous. The running cost of the lighter ambulance is approximately 50 per cent. lower than that of the heavy type. It has not yet been possible to supply all the ambulances the Committee has agreed to allot, but arrears are being rapidly overtaken. The number in each county of course varies with the area and with the character of the population. Durham and Essex have twelve at work; Kent, which asked for twenty, has been allotted twelve, and has ten in use. The West

Riding of Yorkshire is to have twelve, and has now eleven at work; the agricultural East Riding asked for five, and has three at work. The Committee is satisfied with the success achieved during the last twelve months. It is recognized that the variation in the work done in different counties is not always in due proportion to the real needs, but it is hoped that as the scheme becomes better known the use of the ambulances will grow.

MALARIAL PREVENTION.

Dr. C. F. LASSALLE'S report¹ on an anopheles survey of the colony of Trinidad and Tobago furnishes interesting reading. Carried out with great care and accuracy, it should form a standard for work of this nature. It deals fully with all the known methods for destroying and keeping down anopheles, and it points out that many of the recommendations can be carried out efficiently by a small sanitary gang working under the direction of the sanitary inspector of the district concerned. In his conclusions he quotes a passage from Hoffman which is worthy of note: "Rural sanitation and malaria prevention are practically synonymous or equivalent terms and the one, broadly speaking, cannot be achieved without the other. Malaria prevention, to be permanently successful, however, requires the most complete co-ordination of governmental, corporate, and private functions and efforts to the same extent to which this has been the case in Panama, where practically the whole population has been brought under most perfect sanitary control." People nowadays look at the subject of malaria prevention in a much more common-sense manner than they used to, and of course no scientist dreams of exterminating the whole of the mosquitos of an island or other area, though this is what the laity still imagine. Dr. Lassalle refers to this in his report and shows how such ideas retard progress and make the lot of the sanitarian a hard one. Still the new ideas are gradually creeping in, even outside the entomological and medical worlds, and the progress which has already been made should soon be multiplied indefinitely. Those interested in the subject should certainly read Dr. Lassalle's report.

THE TEACHING OF THE MECHANISM OF LABOUR.

THERE are certain subjects in the medical curriculum that are traditionally regarded as stumbling-blocks to the student, and expected to prove such to each generation in succession. How far this expectation on the part of the teacher is father to realization on the part of the taught may be a matter for speculation, but the general effect is detrimental. Amongst such subjects the mechanism of labour has always held a place, and many are the students who would class it along with the better known *pons asinorum* of earlier days. Any plan for the simplification of the teaching of mechanisms without sacrificing scientific accuracy should therefore be welcomed by all teachers, and this is the reason why we would draw attention to an article in the *Indian Medical Gazette* of September, 1920. The writer is Lieut.-Colonel A. Buchanan, I.M.S., lately Superintendent of the Robertson Medical School, Nagpur, and he writes not as an obstetrician, but as one whose main interest is to simplify as far as possible the studies of the students under his educational guardianship. Possibly it is just because he is not an obstetrician that there is a certain freshness of outlook in Colonel Buchanan's method of approaching the subject. At the same time the novelty is essentially in the method of demonstration; the cause of the constituent movements of the head mechanism is not explained. In our view it would be a mistake to regard the author's work as a valid argument for recasting Naegele's teaching as to presentations and positions.

Colonel Buchanan points out that the foetal head, looked at from the side, resembles a semicircle with the occipito-mental diameter as its base. The centre of this half-circle, a point which he calls J, nearly corresponds to the cranio-vertebral junction, and may therefore be regarded as the pivot round which the head "circulates" in flexion or extension. Similarly, a vertical mesial section of the pelvis may be likened to a quadrant of a circle with its centre, r, at or near the subpubic angle. He uses models constructed on these lines to represent the head and the pelvis, and to the centre of the base of the head he attaches a wedge to represent the trunk. The problem is now to pass the semicircle through the quadrant, and the writer shows how an easy passage is only possible when the centre of the base of the head is close to the centre of the quadrant of the pelvis. When this is the case, a radius of the head passes through the pelvis instead of a diameter. In parturition the pivotal point of the base of the head is close to the centre of the pelvic quadrant in occipito-anterior vertex cases where flexion is adequate, in mento-anterior face cases where extension is adequate, and in the case of the after-coming head where the back of the neck is under the symphysis. In all of these the semicircle of the head circulates round the symphysis easily, just as a bicycle wheel circulates within its mudguard, because the two are centred upon the same axle. Contrariwise, when the pivotal point of the base of the head is far distant from the centre of the pelvic quadrant there is difficulty in the passage of the head, as is instanced in persistent occipito-posterior cases and persistent mento-posteriors. The models, which we understand are to be had from the Medical Supply Association, Gray's Inn Road, are ingenious, and calculated to be helpful in making quite clear points which it is not easy to describe in writing with complete lucidity. In addition to the features mentioned, the models may be used to show the essential sameness of the objects of flexion in occipito-anterior vertex cases, and of extension in mento-anterior face cases, as well as how premature extension of the head is apt to lead to rupture of the perineum. Those who are interested in this most praiseworthy attempt to simplify a troublesome subject will do well to read the short original article in our contemporary.

DIABETES INSIPIDUS AND THE PITUITARY.

A STRIKING practical outcome of the great volume of physiological, pathological, and clinical work that has accumulated for many years in connexion with the pituitary is that after injections of pituitary extract the polyuria of diabetes insipidus of hypophyseal origin disappears for about twelve hours; by repeated injections of the extract the patients can thus be given a respite, particularly at night, from the otherwise constant disturbance involved by the polyuria. This therapeutic effect, first pointed out by Farini in 1913, and copiously illustrated in a paper read last year at New Orleans by Professor Lewellys Barker of Baltimore, has been thought to rival that of thyroid extract in myxoedema, but the effect is not only more transient but much more rapid in its onset; thus, an hour after the administration of 1 c.cm. of the extract of the posterior lobe it is impossible to distinguish the urine of a patient with diabetes insipidus from that of a normal person. It is difficult even now to explain satisfactorily the mechanism of this therapeutic success, for the physiological effect of extracts of the posterior lobe and pars intermedia, the cells of which are concerned with the excretion of water, has usually been found to be diuresis; and, conversely, as long ago as 1911, Professor Harvey Cushing pointed out the difficulty of harmonizing the diuresis that may accompany hypopituitarism with the *a priori* expectation that individuals with this glandular insufficiency would show a lowered urinary output. In a critical review of hypophyseal polyuria, based on 117 cases, of which 5 are

¹ Report on Anopheles Survey of the Colony of Trinidad and Tobago. By C. F. Lassalle, M.D., D.P.H., Deputy Surgeon-General and Medical Inspector of Health. Trinidad: Printed at the Government Printing Office, Port of Spain. 1920.

original, Schulmann and Desoutter¹ have gone over the whole subject, and comparatively recently Drs. Kennaway and Mottram² have provided a valuable abstract of the literature. The predominance of males—64 per cent.—among the French observers' cases is thought to be possibly due to the influence of syphilis, and cases of cure after antilithetic treatment are given. The usually accepted pituitary origin of diabetes insipidus has been disputed by Camus and Roussy on the grounds that they produced it by puncture of the base of the brain, near the corpora mamillaria, and that pituitary extract has not any specific curative action apart from the fall of blood pressure and vomiting induced by its sudden entry into the veins. This divergence of opinion is discussed in both the reviews, and Drs. Kennaway and Mottram suggest that the polyuria following experimental injury of the base of the brain is due to escape of pituitary secretion into the cerebral substance, there being some evidence that pituitary extract can produce both anti-diuretic and diuretic effects from the presence of two substances. The antidiuretic effect of pituitary extract, thus shown in the treatment of diabetes insipidus, appears to be due to the direct action on the kidney and not to depend on diminished absorption of water from the intestines. In order to obtain this antidiuretic effect the drug should be given hypodermically, administration by the mouth being unsuccessful unless the fresh gland is given in large quantities, ten to twenty times that necessary in hypodermic injection. The French observers tabulate various clinical forms of pituitary polyuria, and in those associated with Fröhlich's adiposo-genital syndrome, Decrom's disease, and infantilism, both sets of clinical manifestations were relieved by pituitary injections; they draw a distinction between pituitary and other forms of polyuria, and state that in the former the renal permeability is normal, except for water, in regard to which it is exaggerated. Failure of response to pituitary medication may be due to the nature of the preparation, the anterior lobe of hypophysis being inert in this respect.

DIURNAL CHANGES IN THE SIZE OF RED BLOOD CELLS.

DR. CECIL PRICE-JONES, ten years ago, described in the pages of this JOURNAL³ his method of measuring the variations in diameter of the red blood cells by projecting the image of the microscopic field on to a table by the aid of a camera obscura, the apparatus being adjusted for a magnification of 1,000 diameters, so that the cells might be measured with a millimetre scale and expressed in terms of fractions of μ . He has now applied his method for the purpose of endeavouring to explain the considerable variation in the mean diameter of the red cells in the healthy person, adhering to one chosen method of preparing the blood films for the purpose of comparison, as it was found that alterations in the fixing and staining reagents produced changes in the mean diameters of the red cells. The result of his researches has been published in an interesting article in the December number of the quarterly *Journal of Pathology and Bacteriology*. That there is a diurnal variation in the diameters of red cells—namely, a gradual increase during the day and a diminution during sleep—appears from tables which show three sets of observations taken by Dr. Price-Jones during ordinary working days, the first film in the morning being taken immediately on waking. The variations are striking; they amount in some cases to as much as 0.6μ , suggesting that the red cells swell and shrink in association with bodily activity. For example, in one series a quick rise of 0.46μ between 8.20 and 9.20 a.m. was recorded after a short push-bicycle ride with a trailer. By experiment it was found that (a) violent

exercise—for example, the investigator ran as quickly as he could up and down six flights of steps three times, until he felt unable to run any more and was distressed in breathing—increased these changes; (b) gentle exercise—an eight mile walk on a fresh morning—had no apparent influence; and (c) rest in bed—for twenty-four hours, for example, spent in reading, with usual meals—did not abolish these diurnal variations. The facts obtainable from the observations suggested to Dr. Price-Jones that the variations in size of the red cells were due to differences in the reaction of the blood. Experiments *in vitro* showed that the red cells swelled with an increase of acidity, and shrank when the blood was made abnormally alkaline. Several simultaneous determinations of blood reaction and red cell diameters made by the investigator on himself, before and after short violent exercise, showed in each case that an increase in diameter was associated with a diminution in alkalinity. It is already known that at the moment of first awakening in the morning the blood is a good deal more alkaline than later on during the day; and while the kidney produces an acid urine during the night, in the morning it tends to become alkaline, presumably so that the blood may be more alkaline during the night and less alkaline during the day. Taking the work of previous investigators into account, the experiments and observations of Dr. Price-Jones appear to show, therefore, that the diurnal variation in the diameter of red blood cells is presumably due to the altered reactions of the blood; but whether the diminished alkalinity and increased diameters which prevail during the active part of the day are due to accumulations of CO_2 , or lactic acid, or to some other source of altered reaction, we have at present no means of judging.

POST-GRADUATE INSTRUCTION IN PARIS.

EVEN if the tradition that it had its beginnings in the time of Charlemagne be rejected there can be little doubt that the Medical School of Paris is the oldest existing. A faculty of medicine was instituted in 1270; it formed part of the university, was dependent on the faculty of arts, and was subject to ecclesiastical authority. The medical faculty subsequently became independent, but the influence of the old association was shown in the rule, only abrogated in 1452, that the doctor of medicine should be celibate. For a time the Academy of Surgery was a rival institution, but both were suppressed during the revolution (1792), and replaced in 1794 by a single *École de Santé*. This school developed rapidly; the whole system of medical education was reorganized, and clinical courses were established in three hospitals specially equipped for the purpose. In 1808 the school became once more the *Faculté de Médecine*. The medical curriculum now extends to five years, and the State diploma, which alone gives the right to practise in France, is granted only to candidates who have passed through the whole medical course in Paris. Foreign practitioners can obtain, by examination, the diploma M.D. of the University of Paris, but this is a purely scientific distinction. Many of the professors in the faculty have arranged post-graduate courses; such courses will be given this spring in pathology, bacteriology, parasitology and pharmacology. During the summer and autumn there will be special clinical courses in many of the hospitals. Permission to work in the research laboratories attached to the various chairs is granted to suitable applicants at the discretion of the professor. Practical courses in bacteriology, physiology and biological chemistry are given at the Pasteur Institute, and here again suitable applicants may obtain permission to work in the research laboratories. The Institute, it will be remembered, possesses its own hospital for the treatment of infectious diseases. Paris possesses also the Institut Maréy, which is fitted with all the apparatus for the study of movement by the graphic method; it is

³ *BRITISH MEDICAL JOURNAL*, 1910, vol. ii, p. 1418.

administered by an international commission. A Société des Amis de la Faculté de Médecine de l'Université de Paris has been formed to help it in various ways, especially by aiding in the improvement of its equipment and its research laboratories, and, by making French medicine better known abroad, to contribute to the advancement of medical science. This society has recently issued a pamphlet giving full particulars about the facilities afforded in Paris for medical and post-graduate education. Further information can, we understand, be obtained from M. Masson, Treasurer of the Society, 120, Boulevard Saint Germain, Paris.

THE COMING PARLIAMENTARY SESSION.

Our Lobby Correspondent writes: The new session of Parliament will be opened by the King in state on Tuesday next, February 15th. The date is later than usual, and, Easter falling earlier than ordinarily, financial votes are likely to take up most of the time before the first recess. The Government's intention is to limit the legislative programme as much as may be, both for the sake of economy and to avoid autumn sittings. Pledges already given and necessary demands must, however, involve a large amount of business, and it is highly probable that members may show more controversial spirit as the period for a dissolution approaches and constituents have again to be met. The idea of a general election before 1922 is now generally discounted, although circumstances might bring it about sooner than is contemplated. The problem most affecting it will be the passage of a bill for the reform of the House of Lords. Whether this can be achieved by the end of the present session is doubtful; but a measure is promised, and after it has been placed on the statute book a general election will be required within a few months, as the constitution of Parliament will have been changed. Political prophets incline to the belief that this will happen in the spring of next year. Before that reform is attempted a number of other measures have to be faced. Prominent amongst these will be a bill to safeguard key industries, which may also tackle dumping, though that question may be taken up separately. A promise has been given for the reform of the Poor Law, to carry with it the ending of the workhouse system; but that, again, is a big matter which cannot be dealt with rapidly. Licensing legislation presents the same difficulty of needing a good deal of time for careful treatment. More urgent is a bill to clear up affairs in the hands of the Ministry of Transport—a department whose future will depend upon the policy to be determined within the session. The Ministry of Health alone has enough legislative work before it to occupy many contentious weeks in the House of Commons. Apart from the promise, as yet unfulfilled, to bring in a Poor Law Bill there are a host of matters to be proceeded with. First of all comes the question whether the Ministry of Health (Miscellaneous Provisions) Bill, rejected by the House of Lords at the end of last session, is to be reintroduced in the same form. The intention of the Cabinet in December was that this should be done, but there are strong arguments for separating the different proposals which, united in one bill, tended to form such a strong combination of critics against the bill as a whole. It seems quite possible, therefore, that the clause for providing a subsidy for house building may be detached, and that the clauses touching hospitals and homes for the treatment of incipient mental disease may be put into a single measure. No difficulty should be experienced in passing the Tuberculosis Bill, introduced last session, which is designed to transfer the exercise of powers from the Insurance Committees to local authorities, with the grant of certain additional powers to the latter bodies. The Patent Medicines Bill, which was carried to the Report stage in the House of Lords, will, it is hoped, be introduced in the House of Commons as a more or less agreed measure; and the same remark applies to the Dentists Bill, which

was framed on the report of a Select Committee. It is interesting to learn that the valuations of the friendly societies for health insurance are coming out favourably; they are not yet completed, but a large number of the returns to hand show a surplus, and the problem will arise how this is to be applied in increased benefits. Amongst the objects to which it might be devoted are dental treatment, convalescent homes, and, possibly, some allowance for treatment of insured persons in hospitals, which might render a little help towards the solution of the hospital problem. The Committee on Hospital Finance, of which Lord Cave is chairman, is meeting twice a week, and is making good progress in taking evidence.

RED CROSS WAR MEDAL.

The British Red Cross Society has struck a medal for presentation to those of its many war workers who have received no British decoration or medal. Among those entitled to receive it are all members of the society or its voluntary aid detachments who during the war gave a minimum unpaid service at home or abroad of not less than a thousand hours. In the case of ambulance drivers and bearers the minimum number of hours is five hundred. For air raid duty, in the course of which great personal danger was often incurred, there is no fixed minimum period of service, and the Red Cross county presidents will nominate for the medal in their discretion. The medal, which is in gilt with a white ribbed-silk ribbon, is the only one ever issued by the British Red Cross Society. Engraved on the obverse is the well-known symbol, with the words, "For war service, 1914-1918," while the reverse bears the Red Cross motto, "Inter arma caritas." Forms of application can be obtained from the Secretary, British Red Cross Society, 19, Berkeley Street, W.1. Envelopes should be marked "B.R.C.S. Medal." We understand that those entitled to the medal will include medical practitioners who gave gratuitous Red Cross service during the war and have received no British award. The expression "during the war" means the period from August 4th, 1914, to December 31st, 1919.

DANGEROUS DRUGS REGULATIONS.

In the JOURNAL of January 15th we announced the issue by the Home Secretary, under Section 7 of the Dangerous Drugs Act, 1920, of draft Regulations of a most drastic nature for the control of dealings in morphine, cocaine, ecgonine, diamorphine (heroin), and their respective salts, as well as in medicinal opium and in preparations containing not less than one-fifth per cent. of morphine or one-tenth per cent. of cocaine, ecgonine, or diamorphine. That the medical profession would be hampered by them in its legitimate use of these drugs was recognized by the Medico-Political Committee of the British Medical Association, and a protest, on general grounds, was at once made to the Home Office. Since then detailed representations have been drawn up and embodied in a memorandum submitted on February 3rd to the Home Secretary. This memorandum, together with the accompanying letter forwarded by the Medical Secretary, is printed in full in the SUPPLEMENT this week. The matter is one that concerns not only those medical practitioners who dispense their own medicines, but every practising member of the profession. We are all agreed as to the need for restricting, so far as is reasonable, the purchase and sale of habit-forming drugs; but there is a limit to what can be asked of busy practitioners. The official reply to the Association's memorandum has not yet been received, but in the meanwhile a statement by Sir Edward Troup, permanent Under-Secretary of State in the Home Office, has appeared in the Times. He emphasizes the point that the Regulations have not yet been made, and indicates several respects in which the draft seems to have been misunderstood. The Regulations, he explains, have been issued in draft

in pursuance of the Rules Publication Act, 1893, in order that all persons and bodies interested may have an opportunity of considering them and submitting any representations or suggestions before they are finally made; and he adds that all such representations or suggestions will be carefully considered. The medical profession will welcome also Sir Edward Troup's assurance that a doctor will not have to enter the fact in a book whenever he gives a hypodermic injection of morphine or otherwise administers any of these drugs. "The Regulations require certain records to be kept in cases where drugs are supplied, and these apply to doctors who supply medicines to their patients, as well as to chemists who supply them on a doctor's prescription. But there is no requirement that a record has to be kept of a personal administration of the drugs by a doctor." Consultation with the British Medical Association before the Regulations were drafted might, among other benefits, have prevented any misapprehension as to the exact meaning the official mind attaches to the verb "supply."

OXFORD OPHTHALMOLOGICAL CONGRESS.

THE Oxford Ophthalmological Congress will assemble at Keble College, Oxford, on the evening of Wednesday, July 6th next, and the meeting will be held on July 7th and 8th, with an extension to the morning of Saturday, July 9th, if needed. On July 7th a discussion on "The causes of infection after extraction of senile cataract" will be opened by Dr. Victor Morax of Paris. The Congress dinner will take place on July 7th, in the Hall of Keble College, and the Doyne Memorial Lecture will be delivered on the following morning by Dr. Ernest E. Maddox on "Heterophoria." Those wishing to contribute papers, pathological specimens, new operations, cases, or novelties, are asked to notify the Honorary Secretary, Mr. Bernard Cridland, Salisbury House, Wolverhampton.

RAT EXTERMINATION.

AN example of what can be done by the well-directed energy of a comparatively few enthusiasts, concentrating on one piece of work and doing that well, is shown by the results achieved by the Incorporated Vermin Repression Society, the annual dinner of which was held in London on February 8th. This society was the means of pushing the Rat Bill through Parliament, and after that useful object had been achieved it would have been wound up but for the fact that the Ministry of Agriculture urged the society to remain in existence to encourage its special propaganda. At the annual dinner, Sir Bruce Bruce-Porter, who was in the chair, gave figures of the enormous destruction effected annually by rats, and suggested that the Boy Scouts' organization might take up ratting as part of its work, pitting the brain of the scout against the nimble brain of the rat. Professor W. J. R. Simpson spoke on the rat as a carrier of disease, and Professor F. Hobday and others spoke from the agricultural and other points of view. Mr. Alfred Moore, the indefatigable honorary secretary, to whom much of the success of the society is due, mentioned that the society was going to offer its gold medal for the best rat virus that should prove harmless to human beings.

THE Conference of the International Union against Tuberculosis is being arranged by the National Association for the Prevention of Tuberculosis, 20, Hanover Square, London, W.1, and will be held in London from July 26th to 28th. Delegates from about twenty-five countries will attend and take part in the proceedings. Professor Calmette will open a discussion on the modes of diffusion of tuberculosis throughout the races of the world, and there will be three public addresses, given by a Frenchman, an American, and an Englishman. Visits to tuberculosis hospitals, sanatoriums, and laboratories will be arranged.

England and Wales.

PRESENTATION TO SIR ROBERT JONES.

ON January 31st, at the Adelphi Hotel, Liverpool, Major-General Sir Robert Jones was the guest at a dinner, with the Earl of Derby in the chair, on the occasion of the presentation of his portrait, subscribed for by the committee and staff of the Royal Southern Hospital, Liverpool. The portrait shows Sir Robert in the uniform of a major-general A.M.S., and was painted by the well known Liverpool artist, Mr. R. E. Morrison. Former residents and others had come from all parts of the country to be present, and among the apologies were those of Sir Anthony Bowlby, President of the Royal College of Surgeons, and the Bishop of Liverpool. In proposing the toast of "The Guest," Lord Derby spoke in appreciation of what Sir Robert Jones had done, not only during the war, but before the war. He had first known him in connexion with his work for crippled children, and he could never forget the shout of delight of those children when Sir Robert went into a ward once with himself, when visiting the Children's Hospital at Heswall. He described the magnificent work which had been done by Sir Robert Jones during the war in organizing throughout the country that particular branch of surgery which he had made his own. There were thousands of men, he said, at the present moment who were blessing the name of Sir Robert Jones for all that he had done for them. He was not only respected and esteemed as a great surgeon, but he was loved as a friend. Mr. G. P. Newbolt, senior surgeon to the Royal Southern Hospital, supporting the toast in an amusing speech, said that Sir Robert Jones was one of his oldest friends; they had worked together as young men at the Stanley Hospital, and as consulting surgeons for the Manchester Ship Canal works. In 1891, the year in which Sir Robert was appointed surgeon to the Southern Hospital, Owen Thomas died, and the full brunt of that surgical practice fell upon him. His reputation began to grow both on the Continent and in America, and his work in the war only added to an already great name. The toast was accorded with musical honours. Then Lord Derby unveiled the portrait, and in asking Sir Robert Jones to accept it said that Sir Robert would take this portrait away with him, but his friends would ever retain in their hearts a portrait no artist could reproduce.

Sir Robert Jones, in his reply, referred to the help and encouragement he had received from the chairman, when Minister for War, in his work in the military hospitals, especially in the creation of the curative workshops which had proved of so much value. He himself had but endeavoured to apply those surgical principles which had their birthplace in Liverpool, to the treatment of wounded soldiers at home and abroad. Those principles were associated with the name of Hugh Owen Thomas, the application of whose knee splint in the firing line had certainly reduced the mortality of compound fractures of the thigh in the war from 80 to 20 per cent. The first orthopaedic centre which he was asked to organize was opened at Alder Hey, near Liverpool, and the centres rapidly developed over the British Isles until nearly 30,000 beds were occupied. The knowledge gained should prove of immense value to the accidents in industrial life, and it had also resulted in a demand for orthopaedic education as a part of the student's curriculum. Although he was resigning the post of surgeon to the Royal Southern Hospital, he was retaining, in addition to the aftermath of military work, his connexion with various children's hospitals. He alluded to the pioneer work Liverpool, through the munificence of its citizens, had accomplished in the care and cure of cripples, and felt proud that Liverpool had maintained the lead in all that pertained to child well-being.

Dr. J. E. Gemmell, President of the Liverpool Medical Institution, proposed the toast of "The Royal Southern Hospital," responded to by Mr. Thomas Woodsend, president of the Hospital Committee. Dr. C. J. Macalister proposed the toast of "The Guests," responded to by Dr. J. G. Adams, Vice-Chancellor of the University of Liverpool, and by Sir Berkeley Moynihan. Mr. T. R. W. Armour, who acted as organizing secretary of the banquet, and to whose

indefatigable labour its memorable success is mainly due, proposed the health of the chairman, to which Lord Derby replied.

MANCHESTER ROYAL INFIRMARY FINANCE.

The annual report of the Manchester Royal Infirmary now issued, in addition to containing an account of the activities of this great provincial institution, raises some points of general interest in regard to hospital finance. The board, it is stated, have carefully considered the question of the admission of "paying patients," but hesitate to adopt a principle which is contrary to the spirit of the constitution of the Manchester Royal Infirmary. Careful inquiries are made, however, as to the financial status of each patient, and where it is found that patients are able to contribute towards the cost of maintenance while in hospital they are asked to do so. By this means a considerable sum is raised annually, and it is worthy of note that "the patients are almost always anxious and pleased to contribute." About 50 per cent. are quite unable to contribute anything. On examination of the statistics given, it is found that in 1920 £18,912 was received as payments from patients—including £1,870 from local authorities and £8,353 from the Ministry of Pensions after deduction of the proportion paid to the honorary medical staff—the corresponding sum received in 1913 being £4,222. It is pointed out that the sum received from the Ministry of Pensions will diminish and probably disappear in the near future; but one may hope that the income from local authorities as well as from the patients will correspondingly increase. Annual subscriptions, on the other hand, have increased only to £19,993 in 1920 from £11,002 in 1913. Such funds as the Hospital Saturday Fund and Sunday Fund, and congregational and workmen's collections, are surprisingly small, and have not increased to any material extent from 1913. Turning to the statistics of expenditure, the chief increases have been in the cost of provision (£9,630 in 1913, £29,479 in 1920), in fuel, light, and water (£3,498 in 1913, £10,966 in 1920), and in salaries and wages (£11,380 in 1913, £33,235 in 1920). These increases are, of course, general throughout the country.

As in other hospitals, therefore, the income from annual subscriptions does not in any way keep pace with the necessarily increased expenditure, but it must be obvious from these figures that, without sacrifice of the voluntary principle, a considerable income may be obtained by hospital authorities from payments by patients receiving treatment, particularly in a district where, as in Manchester—so far as one can gather from this report—workpeople's funds do not appear to be so thoroughly organized or to contribute so largely to hospital finances as they do, for instance, in Leicester.

Scotland.

EDINBURGH ROYAL INFIRMARY.

It is of interest to note the following comparative figures, which relate to the work and finances of the Edinburgh Royal Infirmary in 1920, as against forty years ago, 1881:

	1881.	1920.
In-patients treated	5,288 (including fever)	13,320
Out-patients	15,000	43,000
Daily average of in-patients	520	875
Average length of stay	31.6 days	24.05 days.
Average of deaths	8 per cent.	6.8 per cent.
Patients at Convalescent House	701	1,158
Daily average of patients at Convalescent House	43	61
Ordinary income	£21,902	£127,125
Extraordinary income	£5,572	£56,415
Voluntary contributions	£13,742	£33,482
Revenue from investments	£4,418	£16,838
Ordinary expenditure	£31,720	£130,667
Cost per bed	£61	£149 6s. 6d.
Stock and funds	£39,631	£479,031
Nurses and probationers on staff	101	312

OVERCROWDING OF MEDICAL STUDENTS IN GLASGOW.

In order to cope with the conditions attendant on the present overcrowding in the Faculty of Medicine at Glasgow, the Students' Representative Council at

Glasgow University have urged upon the Senate the need for certain improvements. The following resolutions have been approved by the Senate:

That in the departments of anatomy and physiology the staff of demonstrators be increased and more demonstrations given; that the number of hours' laboratory practice in anatomy be published in the calendar and no longer left to the decision of the professor; that the classes of fevers, diseases of sick children, and midwifery be confined to senior students; that the number of students attending the classes of fevers be increased; that three examinations be held annually in second and fifth professional years only. Final examinations to be held twice yearly, while the application by service students for a final in June will be considered.

Other proposals are still under consideration.

CARE OF LIMBLESS MEN.

The annual report of the Princess Louise Cottage Hospital for Limbless Sailors and Soldiers, Erskine, points out that while the number of pensioners admitted to hospital for treatment was diminishing in number, the pensioners who returned to Erskine for training had greatly increased. Since the hospital was opened, until the end of last year, some 6,146 in-patients had been admitted, about 9,496 patients had been fitted with new limbs and repairs to limbs, and 318 pairs of surgical boots had been supplied. The number of major operations was 69, making a total of 470 since the hospital was opened. Reference is made in the report to the services rendered in limb-making and fitting in the workshops and in the training of men for various trades. At the fourth annual meeting of subscribers, held on February 4th, in the City Chambers, Glasgow, Sir William Macewen recalled that when the hospital was launched he had pointed out that it was not the first issue of limbs alone that had to be provided for. Artificial limbs needed to be readjusted, repaired, and renewed throughout the lifetime of the men, and a generation would pass away before all the work connected with the limbless men in the great war was at an end. A great number of the men thought that, now that a little fuss had been made over them, they were to be forgotten. After speaking of the need for subscriptions, Sir William Macewen referred to the inquiry by the commission to which he had given evidence as to the future possibilities of the hospital. While he was not at liberty to speak meantime on that subject, they could rest assured that things were being fairly satisfactorily arranged. The workshops and everything else in Erskine were ready now to be made use of. They could take in quite a number of the severely disabled men, and he hoped arrangements would be made by the Government whereby such men could take advantage of the hospital, and the Government could subsidize or pay maintenance allowance for a certain number of them. Mr. David McCowan, in moving approval of the annual statement of receipts and expenditure, said that the funds they had raised showed that the people of Scotland, and particularly the West of Scotland, could rise to the occasion, especially when it was for the benefit of wounded soldiers. The motion was adopted. On the motion of Lord Blythwood a vote of thanks was accorded to the surgical and medical staff.

Ireland.

We regret to announce the sudden death of Dr. J. C. McWalter, late High Sheriff for the City of Dublin, who was well known in public and professional life in Dublin. We hope to publish an obituary notice in an early issue.

REPRESENTATION OF QUEEN'S UNIVERSITY IN THE ULSTER PARLIAMENT.

A joint meeting of the County Derry Branch of the Irish Medical Association and County Branch of the Irish Medical Committee was held in the Town Hall, Coleraine, on January 28th. Dr. Creery occupied the chair, and there was a large attendance of members. Dr. Charles Forsythe, J.P., moved two resolutions, one expressing the opinion that of the four seats allotted to the Queen's University in the Ulster Parliament at least two should

be held by graduates outside the Belfast area; and the other

"That, in recognition of Dr. H. S. Morrison's long service on behalf of medical and social reform, we nominate him as our candidate, and we commend his claims to all the branches of our associations and to the graduates of the university generally."

Dr. LENNON, J.P., Kilkeel, Secretary, Dr. Magowan, Maghera, and Dr. Thompson, J.P., Bellaghy, supported the resolutions, which were unanimously adopted.

KING'S PROFESSOR OF MATERIA MEDICA.

Dr. T. Gillman Moorhead, Visiting Physician to the Royal City of Dublin Hospital, has been elected by the Royal College of Physicians of Ireland to the King's Professorship in Materia Medica in the School of Physic in Ireland. The vacancy was created by the resignation at the close of last year of Dr. Walter George Smith, who had held the chair for many years. There are four King's Professorships at the School of Physic—in practical medicine, in materia medica and pharmacology, in the institutes of medicine, and in midwifery. The Medical School of Trinity College, Dublin, founded in 1711, was incorporated in 1800 in the School of Physic in Ireland, established that year by Act of Parliament, and was placed under the joint control of Trinity College and the Royal College of Physicians of Ireland.

Correspondence.

SIR JAMES MACKENZIE'S THEORY OF DISTURBED REFLEXES.

Sir,—Granting the possibility of changes in reflex arcs of such a kind that an abnormal response is brought about, there seems no doubt that the phenomena must play a very important part in the symptoms observed in various diseased conditions. A few remarks from the point of view of a physiologist may perhaps be of some interest in the discussion.

Sir James Mackenzie refers to the action of strychnine, tetanus toxin, and similar agents which cause inordinately reflex convulsions. I believe the nature of this effect was first analysed by Sherrington and shown to consist in the reversal of what is normally an inhibitory action by the afferent stimulus on the motor centres of the antagonists of those muscles concerned in the reflex movement, so that the result is simultaneous contraction of opposing muscles. This conversion of inhibition to excitation is particularly disturbing when inhibition is the chief part of the innervation process, as in opening the mouth by relaxation of the temporal and masseter muscles. As Sherrington points out, the greater the effort to open the mouth, the more powerfully it is closed, on account of the great power of the muscles which close the jaw compared with that of those that open it. This above mentioned reversal was worked out by myself in its application to vasomotor reflexes, and it appears to be a very general phenomenon in nervous processes. I was also able to show that the pharmacological antagonists of strychnine, such as chloroform, chloral, etc., have the opposite effect in vasomotor reflexes, in that they convert the excitatory process into an inhibitory one, and it was shown soon afterwards by Sherrington and Sowton that the statement applies also to reflexes to voluntary muscles. The sequence of events in such a case as the effect of strychnine on the depressor reflex in the rabbit, may be of some significance. As the dose is gradually increased, we see at first an exaggeration of the normal vaso dilator effect; this is step by step converted into a vaso constriction and ultimately paralysed altogether. It appears as if reversal were a stage in the paralyzing action.

It is not to be understood that reversals of this nature are only of toxic or pathological origin. They make their appearance in normal neural processes, as shown by the following experiment due to Magnus. The direction of the movement of the tail of a spinal cat, when the tip is pinched, varies with the position in which it hangs. This movement is always towards the stretched side, so that the same afferent impulse produces in one position excitation of those muscles which are inhibited in the opposite position. The condition of the centre must be changed by

receipt of afferent impulses from the stretched muscle. Sherrington and Graham Brown, moreover, showed that the sign of the effect from a particular cortical point varied according to whether other points were stimulated at the same time, and whether the point itself had recently been in activity. Thus, as is so frequently the case, the morbid process is essentially a running wild, as it were, of a natural one.

But in any case we realize what a wide field of research is opened up in the interpretation of symptoms on lines akin to this. It will be generally admitted that very little, if any, advance is made by the mere multiplication of symptoms recognized unless we know more about them. They may be merely indirect results of previously known ones. The analysis must be pushed further back in the way indicated by Sir James Mackenzie, while the correct recognition of the less obvious signs will greatly assist in this. We see also how the possibility of disturbed reflex warns against hastily assuming a local manifestation to be due necessarily to a morbid process in this particular place.

Sir James Mackenzie points out that there may be a disturbance in the receptor or effector part of the reflex arc as an additional possibility to that already referred to concerning the nerve centre or adjustor. I may recall certain facts which suggest that an agent which normally produces a contraction of smooth muscle, by stimulation of the peripheral myoneural junction, may be reversed in its action by the presence of a toxic substance, so that it now causes relaxation or vice versa. This suggestion was made some years ago by Dr. H. K. Anderson, in explanation of the experimental fact, found by Elliott, that the contractile action of adrenalin may be converted by ergotamine into an inhibitory one. I subsequently put forward the same view myself, in ignorance of Dr. Anderson's having previously done so. A similar effect is that described by Langley in the case of the bladder, in which stimulation of the sacral nerves causes inhibition after nicotine or curare, in place of the normal contraction; and that by Dale and Laidlaw, in which it appears that cytisine may convert the normal secretory effect of the chorda tympani nerve into an inhibition of secretory activity already in progress.

Our attention is also directed to the part played by the process called "facilitation" by Sherrington. In this a stimulus, itself below the threshold of activity, is made active by the simultaneous play of stimuli from other sources upon certain neurones in the course of its passage through the nerve centres. This is pointed out as being of especial importance in correctly estimating the value of symptoms of pain.

I thoroughly agree with the emphasis laid by Sir James Mackenzie on disturbances of blood supply. It is clear that a vital organ may suffer from want of oxygen, not only owing to failure of the heart or loss of circulating blood, but also from a local spasm of arterioles, which may well be due to a disturbed reflex.

Although I can lay no claim to express any opinion on clinical matters, it seems to me that the disturbance of reflexes described must undoubtedly take place, and, if so, a powerful means of analysing and interpreting the complex symptoms of disease has been provided.—I am, etc.,

London, N.W., Feb 3rd.

W. M. BAYLIS.

Sir,—The question of definition of the word "symptom," asked by my friend Dr. Harry Campbell, is one which has been the subject of much deliberation. In a sense the definition depends upon the use one intends to make of the definition. If it is only for purposes of abstract reasoning, one may easily become lost in a maze of logomachy, but if it is to be employed in the examination of patients there are several definitions of value. For this latter purpose we define *symptoms* as the reaction of the tissues to an injurious agent. We use the term freely, and do not differentiate it from sign—using the terms symptom, sign, and manifestation of disease interchangeably. By and by we may get a clearer definition, but the above definition represents the state of knowledge which we have reached.

Dr. Halliday Sutherland's objection to consumption being a secondary disease is possibly quite valid. In my twenty eight years in general practice many of my patients developed consumption, but my recollection is that all, or most of them, were ill for years and frequently under my

care for a variety of complaints. It occurred to me that their complaints may have been due to conditions which predisposed to consumption. I quite realize that these preceding complaints may have been due to the action of the tubercle bacillus before declaring itself in the lungs. It shows the need of recognizing the symptoms produced by the invasion of the tubercle bacillus.

The well known fact that certain infectious diseases and certain drugs—which act as imitation diseases—give rise to a peculiar grouping of symptoms suggests that many obscure illnesses are due to a definite toxic agent. These agents may be recognized, not by the peculiarity of one symptom but by the peculiar grouping of symptoms. We find that many symptoms are common to a great many widely different disease agents, but that each agent produces a peculiar grouping of these symptoms. Though we recognized this, we made little progress until we found that there was some mechanism which was capable of producing a great number of symptoms, and thus we were led to the recognition of disturbed reflexes being this common mechanism.—I am, etc..

The Clinical Institute for Research,
St. Andrews, Feb. 7th.

J. MACKENZIE.

A PROFESSOR OF MILITARY MEDICAL HISTORY AT THE R.A.M. COLLEGE, LONDON.

SIR.—We need at the Royal Army Medical College a Professor of Military Medical History, working exactly on the same lines as a Professor of Military History at an ordinary military college.

This suggested professor would trace out in his lectures the evolution of medical aid in war—and deal from the health point of view with the evolution of sanitary science—in our own and other armies. The tragedy of the Crimean war has gradually been forgotten; all that Walcheren stood for is wellnigh unknown, and we need to go back decade on decade into the history of the wars of the French Revolution and the Napoleonic era. I grew up in the army in the midst of the Crimean military surgeons, heard all the miserable story of the Crimean winter, and received from such descriptions an intense stimulus to army medical war developments. I sat for long hours, and times without number, listening to the story of Florence Nightingale's experiences from her own lips, and so needed no professor to stimulate my efforts at war betterment.

The moment the R.A.M.C. officers know that such a professorship as I propose will be founded their study of military medical history will be developed and further readiness for war responsibility will result. The cost of the professorship will be about £1,000 a year, and it will repay the nation hand over hand by its results. I do not now refer to sanitary science or military hygiene only: I include personnel, hospital administration, field medical discipline, the disposal of wounded in the past. One day, when we are better friends of the army officers, they will send us their professor of military history to give fourteen lectures each year, and we will repay the compliment by lending our professor of military medical history.

Till this combination comes complete success is impossible.—I am, etc.,

GEORGE J. H. EVATT, M.D.,

Major-General Army Medical Staff (retired).

Junior U.S. Club, Charles Street, St. James's,
London, Feb., 1921.

SUGGESTIONS FOR A CO-OPERATIVE HEALTH SERVICE FOR LONDON.

SIR,—It is curious how often people may be thinking and working on the same lines quite unknown to each other. Whilst Brighton has been evolving its provident scheme, I have been working out a possible health service for London on very similar lines. The Brighton scheme, however, is apparently intended primarily for insured persons, whereas mine is intended in the first instance for that large section of the community whose incomes exclude them from the benefit of the National Insurance

but who are nevertheless unable to provide for themselves the present costly methods of diagnosis and treatment. To secure for them a complete health service, at Glasgow, general practitioners, consultants, and specialists, opened health centre and a private hospital is the

main object of the scheme, but seeing that there is at present no organized service of consultants and specialists under the National Insurance Act, such services would be thrown open to insured persons at specially arranged subscriptions. That the middle classes, who have been especially punished by the war and the high cost of living, require some method of obtaining the advice and treatment they require is hardly open to doubt, and from a study of statistics of the population and of the income tax returns I feel sure that it could be provided with great advantage to themselves and to the medical profession on the principles of insurance, whereby each breadwinner or income owner would pay a yearly subscription for himself and his family to cover the risk of requiring medical advice and treatment. The subscription would vary with the income earned or possessed and with the size of the family. Those earning under £300 a year would pay £1 15s. a year for himself and a similar sum for each member of the family, and the subscription would rise to £5 or £6 for larger incomes, and even more according to the limit decided upon, as shown in the accompanying table.

Subscriptions per Head of Insured Persons.
Unit of 1,000 Breadwinners and 1,600 Insured Persons, representing 4,240 Souls.

Incomes.	Breadwinners.	Bread-winners and Dependents.	Annual Subscription per Head.
Under £250	1,000 nationally insured.		£ s. d. 1 1 0
£ 250 — 300	325	1,052	1 15 0

Breadwinners ..	1,000	4,240	
Nationally insured .	1,000		

In explanation of this table it must be pointed out that, according to the last census, in every 1,000 breadwinners over the age of twenty 300 are unmarried and 700 are married, and that each married couple is on the average responsible for 2.2 children; also that the number of persons earning the specified incomes are taken from income tax returns. The figures, as will be seen, are based upon a unit of 1,000 breadwinners with their families and 1,600 nationally insured persons. With 3,000 or 4,000 subscribing breadwinners the annual subscriptions could be reduced by 20 or 25 per cent.

The yearly subscription would entitle the subscriber to the services of a general practitioner, to medical aid in confinements, to the advice and help of consultants and specialists, to operative treatment, to the use of the equipment at the health centre, and to admission to hospital.

With the suggested scale of subscriptions general practitioners could be paid double the present capitation grant for nationally insured persons, and 5 guineas for each confinement. Consultants and specialists could be paid at any rate the usual pre-war consultation fees, and an average of about 35 guineas for operations. If subscribing members were admitted to voluntary hospitals, a donation of about £4 a week could be made to their funds, and the contemplated private hospital would do something to relieve the congestion of their waiting lists. Finally, when all these payments had been met, there would be a substantial balance for the running costs of

the health centre, which might eventually become a "Mayo clinic" for London.

At the present time a greatly extended scheme of compulsory insurance seems to be in the air, and this would not, I believe, be welcomed by those who have had experience of the working of the National Insurance Act. A voluntary scheme such as is here outlined would have the great advantage of keeping its control and management in the hands of medical men and their patients, and it might in time solve the whole question of an organized medical service "available to all citizens," such as the Dawson Report deems to be so necessary for the health of the individual and of the community. If successfully launched in London it could easily be extended to the provinces, and eventually to the whole country.—I am, etc.,

London, W., Jan. 27th.

CHARLES A. PARKER.

THE RISKS AFTER OPERATIONS FOR TONSILS AND ADENOIDS IN OUT-PATIENT CLINICS.

SIR,—I should like to thank your numerous correspondents who have shown their interest in the question raised in my original contribution in your issue of December 11th, and who have added so much valuable information. My purpose was simply to submit evidence that the risks of serious complications, even with carefully selected cases, are far greater when the patients are sent home soon after the operation than when they are kept in hospital for a day or two.

In some hospitals there is sufficient in-patient accommodation, and the operation can be performed under conditions which minimize the risk of complications, and which add greatly to the comfort of the children. In others, pressure upon beds renders this impracticable. Some of your correspondents have offered useful suggestions whereby the difficulty may be overcome.

It may serve a good purpose if I venture to draw attention to the recommendations in the Report for 1919 of the Chief Medical Officer to the Board of Education, Sir George Newman. Followed to their logical conclusion these leave little to be desired, and are in advance of the practice in some hospitals with special clinics. He emphasizes seven "points as regards arrangements for the operation which experience proves to be important." These include proper preliminary preparation of the child, a competent anaesthetist, and a skilled operator, and further—

"beds should always be available; primary subsequent care of the child in order to protect it from chill, dust, fatigue, and septic and other infections; secondary subsequent treatment . . . medical and nursing supervision during the days immediately following the operation . . . ; and partly after-care treatment, including appropriate and prolonged remedial and breathing exercises. All these matters, it should be noted, are important, not only to avoid accidents (for in any case these are extremely rare), but to secure the full and proper advantage of the operation."

—I am, etc.,

E. WATSON-WILLIAMS,
Surgeon for Diseases of Ear, Nose, and Throat,
Southmead Hospital and Royal Hospital for
Sick Children and Women, Bristol.

February 7th.

THE BRADFORD MUNICIPAL GENERAL HOSPITAL.

SIR,—In the JOURNAL of January 15th the above hospital was crushingly dismissed by Mr. Hall as "the same old obsolete group of buildings which the Local Government Board condemned as unfit for hospital purposes twenty years ago." It now appears (vide JOURNAL of February 5th) that what he really meant to say was that the Municipal Hospital "is a group of buildings unsuitable for the requirements of a general hospital," a portion of which (280 beds) was erected sixteen years ago, and sanctioned by the Local Government Board for hospital purposes. The present unsuitability of these buildings he ascribes to their having been "built for Poor Law purposes under the Poor Law regulations," and consequently to their sharing with many general hospitals the disadvantage of providing less than 1,500 cubic feet per bed. There is no criticism of their construction, lighting, heating, equipment, cleanliness, or nursing facilities; their condemnation rests solely on the inadequacy of the space per bed, which, in the buildings under discussion, is 1,115 cubic feet.

This deficiency could, of course, easily be remedied by

a reduction of 20 per cent. in the number of certified beds. By doing this all round, the Bradford Municipal Hospital could provide more than 1,500 cubic feet for each of 900 beds.—I am, etc.,

Bradford, Feb. 6th.

B. HOLROYD SLATER.

THE PREVENTION OF VENEREAL DISEASE.

SIR,—I am much obliged to Mr. E. B. Turner for the good opinion he expresses of me in his review of my book (BRITISH MEDICAL JOURNAL, January 29th). I hope my intimates, who are sometimes disrespectful, will read and inwardly digest. But Mr. Turner suggests that I exaggerate, and that I am unfair to the Royal Commission on Venereal Diseases and to the National Council for Combating Venereal Diseases.

As to exaggeration. After insisting in the beginning of the book that I am not in a position to estimate the prevalence of venereal disease from facts within my own knowledge, I give the official figures, and invite the reader to form his own opinion; but, of course, I state what the figures appear to mean to me—that is, if 10 per cent. of the population of the large towns suffered from syphilis before the war, if gonorrhoea is many times more prevalent than syphilis, if both diseases have since increased, if 79 per cent. of the population is urban, and if three out of four men get their infections from amateurs, the estimate that about half the population has been infected does not appear excessive to me.

As to the Royal Commission. This body was appointed "to inquire into the prevalence of venereal diseases in the United Kingdom, their effects upon the health of the community, and the means by which those effects can be alleviated or prevented." *Prevented*, be it noted. Metchnikoff published his discovery in 1906. The medical world rang with it. When the Royal Commission published its report in 1916 that discovery was under employment for the protection of the British Navy and some 20,000,000 soldiers on the Continent. Yet the Commission ignored Metchnikoff and prevention, and left the Government and the public to infer that there was no such thing. We have, then, two alternatives. It would be interesting to know which of them Mr. Turner prefers. Either the Commission was so ignorant that it had never heard of Metchnikoff and prevention, in which case it was intellectually unfitted for its task; or else it deliberately suppressed the truth, in which case it was morally unfitted for its task. As a fact, some of the medical members were anxious to consider prevention, but were told that any attempt to deal with it would wreck the whole inquiry.

The Commission warmly commended to the Government for its future guidance the newly formed National Council for Combating Venereal Diseases. In other words, it warmly commended itself; for the chairman of the one became the president of the other, and was followed by many members of the Commission to the directorate of the Council. At first it was proposed to call the latter "The National Council for the Prevention of Venereal Disease," but "Prevention" suggested the accursed thing and was changed to "Combating." To this day the lecturers of the Council are forbidden to mention prevention. The Council, a self-appointed body of private people, warmly supported by such dignitaries as the Archbishop of Canterbury, became extremely influential with a Government that was anxious to evade unpleasant responsibilities, and has been entrusted with the expenditure of increasingly large sums of public money. So financed, some of its members are now touring the world spreading the light as revealed to them. At least they will see the world. The policy of the Council has three principal features: (1) Morality is preached to adults and adolescents who, having already received their bias, have become unteachable, as any reader of the BRITISH MEDICAL JOURNAL may judge by examining his own consciousness and considering what effect moral lectures would produce on, for example, errand boys, factory hands, university undergraduates, and medical students. (2) The horrors of disease are expounded to prospective sinners who are thereby frightened from prostitutes to the pursuit of amateurs. (3) Clinics are thoughtfully provided to meet the resultant increase of disease.

Mr. Turner says that one of the most distinguished members of the Council was active in establishing the army venereal ablation rooms. But that is precisely what

I indicate in my book; I say that "a sort of bargain was made." In 1916 venereal disease was draining the army, and there was a dearth of trained men. The authorities wished to issue packets, which, though unnecessary in view of the abundant disinfectants available, would have constituted an attempt to bring quick disinfection within reach of every man. But "influential people" intervened, and the ablution rooms for "early treatment" were established instead—that is, for delayed and inefficient disinfection available only for men in camps and barracks. Later, dissatisfied with the results, I told the men in my charge:

"I have talked to you till I am tired, and you will go wrong. But I will not have you bringing these beastly infections into barracks where they are a danger to your comrades. In future, if you think you are likely to go wrong you must carry disinfectants and use them at once. If you bring a small bottle and ask my orderly, he will supply them."

After that for six months I had not a single case of venereal disease, and during twenty-eight months my rate of infection was 1.5 per 1,000 per annum. In the garrison generally it was 92. One officer wrote that owing to the nature of their duties he could not send his men for instruction; would I give him the heads of a lecture? I wrote a discourse in full, and a copy of it got into the hands of the authorities and was by them printed as a "specimen lecture" for medical officers. But it was altered. All my moral platitudes were left unchanged; but the gist of it—the insistence on immediate disinfection—was replaced by an injunction to get the disinfectants after return to barracks and then seek some retired place, "a w.c. or dark doorway," and there disinfect. Conceive it: the men were not even to disinfect as before in the ablution rooms. Imagine a sergeant-major—all sergeant-majors are great sticklers for the conventions—catching a man swabbing himself in a barrack doorway! The thing would have been positively dangerous. These sapient alterations were made, characteristically enough, by just that active and influential member of the National Council who, as Mr. Turner says, was so zealous in establishing the venereal ablution rooms. Still later, when the authorities resolved—in spite of the protests of those with whom I was associated—to introduce packet instead of instruction, the potent "influential person" again intervened, and the packets were used for "early treatment." Then followed the statistical acrobatics of the Ministry of Health which I described in my letter to the *BRITISH MEDICAL JOURNAL* of January 22nd.

Mr. Turner says that my advocacy of quick disinfection is built on "some extraordinarily good results" obtained by Surgeon Commander Boyden and me. He is good enough to attribute my success to "the fact that he is an extremely able, enthusiastic, and energetic man." But equally good results (described in my book, but not mentioned by Mr. Turner) were obtained in India and all over Hampshire and Dorsetshire. Were the scores of medical officers concerned all "extremely able, enthusiastic, and energetic"? I think myself that their distinguishing peculiarities were a genuine desire to prevent disease and the possession of a modicum of common sense.

But Mr. Turner appears to have done even better by means of moral teaching. "The result of a lecture was that . . . while that unit remained at the dépôt the number of cases of venereal disease diminished from 50, 40, 30, as the case may be, to 3, 2, 1, or none." Think of the splendour of that achievement! Can any reader of the *BRITISH MEDICAL JOURNAL* imagine his ideas of right and wrong and conduct being so profoundly altered by an hour or two of eloquent talk? Yet the like was done, and even among soldiers. But think also of the slackness and turpitude of the Government—with me, as the readers of the *JOURNAL* know, a favourite theme. Here was Mr. Turner giving occasional lectures for the National Council, and he would have been cheap to the nation at a million a year. I hope Mr. Turner will join in pressing for that inquiry into the past which the Society for the Prevention of Venereal Disease advocates.

Several correspondents have asked why the National Council and the Society, which are both anxious to reduce the prevalence of venereal disease, do not sink their differences and consult as to a common policy. Because they are separated by much more than a mere difference of opinion. It is necessary to speak bluntly. It is alleged that the truth has been suppressed, the untruth suggested,

and that there has been an actual falsification of records. The Society for the Prevention of Venereal Disease earnestly desire an authoritative inquiry into the past, feeling that otherwise—no matter what promises are made or what agreements contracted—it cannot trust the future. I speak only for myself, but I feel sure that if both societies unite in promoting such an inquiry all grounds of disagreement will soon vanish.—I am, etc.,

Southsea, Feb. 7th.

G. ARCHDALL REID.

Sir,—I am probably right in assuming that the members of the Society for the Prevention of Venereal Disease do not carry prophylactics for their own use, do not instruct their sons to do so, and do not see that their own children are instructed from an early age in the nature and danger of venereal disease and the methods of prevention. If I am right, what is the reason?

Doctors possess the racial instinct as other men, and are exposed to the same temptations, but they are trusted by their wives and patients, they are expected to be moral, and the very idea of the abuse of that trust is abhorrent to them. They have a moral control which is far stronger than the chemical aids to immorality which are advocated by the Society.

If this moral control is sufficient for doctors, it should also be sufficient for clergymen, lawyers and all men in a position of trust, for all those who are trusted by their wives, and for those who hope to marry pure women and have healthy innocent children. It may not be sufficient for those living in overcrowded unhealthy slums, but the remedy here is obviously one of bricks and mortar, and not one of chemicals.

I have five sons and two daughters and am alarmed by the propaganda carried on by this society. Any man or woman who allows a youth or young girl to believe that there is any necessity for them to give way to temptation does incalculable harm. I am grateful to the Medical Women's Federation for their opposition, and my alarm is lessened when I see that this opposition makes Sir Bryan Donkin forget his chivalry—an indication that his case is a losing one. I believe that when we are able to think in terms of peace we shall realize that measures that may have been advisable in the segregation of camps or in the neighbourhood of the battlefield are harmful and vicious amongst a civil population.

There is no reason why a healthy sane man should be unable to control his natural instincts, and if every woman would insist that men can and must keep straight, this society, which is lowering the moral standard of the country, would soon cease to exist. I believe that the men and women of this country are much more moral than the members of this society would have us believe. I am convinced that the only sound method by which we can really prevent venereal disease is by raising the moral standard, and by educating people, especially women, to realize that there is no necessity for men to give way and risk infection.—I am, etc.,

Reading, Jan. 31st.

S. GILFORD.

Sir,—The nation will eventually be grateful to those who are endeavouring to enlighten it. But while few would accede to the doctrine that preaching the use of disinfectants constitutes the sin of apostasy, others naturally hesitate to advise what they think might lead to immorality.

Little has been said of the loss of moral tone that is a sequel of venereal disease. The nervous system suffers. Periods of excitement lead to further excesses, and this involves spread of the disease. Depression is relieved by drinking. The general effect may well be set off against the possibilities involved in a widespread knowledge of disinfectants. Perhaps this argument—and it becomes more powerful the more carefully it is examined—may induce some to modify their views in opposition to the new proposals.

I think it is true that when man is in the mood he cares little either for morals or microbes. But it is equally true that, if not in the mood, if a petticoat does not move him, permanganate will not do so. Aristotle quotes Homer as to "Charms that do steal the reason of the wise." Elsewhere, writing of sexual pleasure, he says, "No one engaged therein can think at all." In his saner mood man will reason correctly, but when moved by desire good

resolutions vanish. That this mood is periodic is recognized, and if a man can tide over the mood the period passes. This is the crux—how to get clear. The only common remedy I know is hard exercise and a purge. But many regard such advice as comic and stupid.

Early environment counts for much. Those growing up in crowded tenements are habituated to sexual knowledge. They are apt to regard the sexual pleasure as lawful, one akin to eating and drinking. Erotic literature and pictures are another factor. A campaign against these stimulating evils is needed.

There is one strong argument that affects most men. No ordinary sane man desires his wife's death by a repulsive disease, or her change into a feeble and useless creature. None desire hideous or deformed children. Even the wildest young bachelor has lying in his inner consciousness the hope of having healthy children eventually. Working upon this feeling—in itself part of the great law of reproduction—great success may be anticipated. I am inclined to suggest that we leave women out of the discussion for a time and tackle the men only. The reproductive process has two stages: (1) Initiation by the male, (2) conservation by the female. When the men fully grasp the position the women will follow suit.

If these considerations be approximately correct—and there is much others have written which must be included—we may find a common basis, which perhaps all will accept, and which might be formulated as follows:

1. Spr. effects of venereal disease, diseased children.
2. Inst advantages of continence in rendering a boy fit to hold his own in games and studies.
3. Teach the practical value of hard exercise and a purge, perhaps bromides, in tiding over periods of stress (the nerve storm is the real crux, as I have said).
4. Add: "But if you will make a beast of yourself, at least remember possible children, and use disinfectants."
5. Encourage men of all classes to join the Alliance of Honour, for definite short periods, with renewals.

I have for many years talked to officers and their men upon these subjects, and in my last Division I distributed a pamphlet (a copy of which I enclose). Later I saw many well-thumbed copies, and old soldiers expressed their appreciation. I speak of these results as evidence of receptivity. Although it is the reproductive principle that urges men to excess, another factor of the same principle is our strong ally—the love of children—and I feel sure we can make great use of this in our campaign.—I am, etc.,

T. M. CORKER,

Bournemouth, Jan. 1st.

Major-General A.M.S. retired.

SIR.—Mr. Kenneth Walker's letter in your issue of February 5th, expressing in the main opinions with which my Society are cordially in agreement, yet shows that he shares with many others a misapprehension of the origin and scope of the Society for the Prevention of Venereal Disease.

This Society was founded solely to fill in the gap in the propaganda of the National Council for Combating Venereal Diseases left by their opposition to instruction of the public in the prevention of infection by means of immediate self-disinfection. My Society, while freely acknowledging that immediate self-disinfection is only one of many methods for diminishing venereal disease, believe that this method is an extremely important and valuable one, and our propaganda is devoted solely to bringing this method before the public, not because we are in any way whatever antagonistic to other methods, but because this method was not only neglected but actively opposed by the National Council for Combating Venereal Diseases. Our work is not in opposition to but complementary to that of the National Council.

In order to obviate overlapping, we confine our work to giving publicity to the one method not included in the useful nal Council for tion that we the single founded on ignorance of our published statements.

Again, we have times without number pointed out that we do not advocate the packet system, and in our letter

published in the *Times* of October 13th, 1919, which defined our policy, we stated:

"We decline to accept the description of our policy as 'the issue of prophylactic packets to the civilian community' in the way in which they were issued to H.M. Forces. No suggestion has yet been made by our committee as to the methods or means by which the public may obtain the necessary disinfecting material, the fact that such materials are easily obtained at any chemist being in our opinion quite sufficient. The aim of the committee is solely the instruction of the public."

Mr. Walker has summed up our wishes in his sentence, "let each of the societies work along the line it has chosen." My society would welcome the teachers of moral prevention as allies working along another line towards the same goal, if they on their part would accept the alliance of the teachers of medical prevention, and not waste valuable energy in opposition that is not only unnecessary but also hopeless as long as disinfectants are acknowledged to disinfect.—I am, etc.,

London, W.1, Feb. 4th.

H. WANSEY BAYLY.

STAG'S ANTLERS AND EVOLUTION.

SIR.—In the notice of Sir William Macewen's book on *The Growth and Shedding of the Antlers of the Deer*, in your issue of February 5th, your reviewer says:

"When regarded from the evolutionary point of view the stag's antlers are a great puzzle. It is not easy to see that they serve any purpose which, even if they grew once for all, would be commensurate to the expenditure of energy and material; as the antlers are shed annually, the puzzle becomes greater."

I venture, however, to think that from the evolutionary point of view the explanation is simple. It is obviously desirable that the fittest stag should perpetuate its kind, rather than the less fit, and if, after all the expenditure of energy and material associated with the annual development of the antlers a stag outlives its fellows in the struggle for the possession of the female, surely this is a very tangible proof that it is the fittest. If it were merely a question of the survival of the somatic individual, the expenditure on antler growing would no doubt be puzzling, but evolution puts very little importance on the individual *per se*.

The points referred to, namely, great expenditure of energy, the selection of the male which expends most, and the unimportance of the individual provided it achieves success in reproducing its kind, are simply illustrated in the case of the bee. The queen bee in her nuptial flight flies to an extraordinary height, and then only lets success fall on the drone in the swarm following her which is most powerful and energetic and proves it by leaving all the others behind. Having performed his function in life he falls dead.—I am, etc.,

London, Feb. 5th.

J. SIM WALLACE.

X-RAY RADIATION AND CANCER OF THE BREAST.

SIR.—The question of treatment by x radiation has long since passed from the sphere of academic discussion into that of practice. Every practitioner now knows that there are many patients whom he cannot honestly advise on the best course of treatment without a more or less intimate knowledge of x radiation and its influence on the normal and abnormal cells of the body.

In the case of various non-malignant diseases of the skin, etc., such knowledge is a refinement which possibly he may neglect and leave to the whole-time specialists in this subject.

In the case of malignant disease, however, this seems to me wrong, for we are here dealing with the immediate issue of life and death to the patient.

It is unfortunate that the problem in the latter case is more difficult than in the former, but just here the question of dosage is one of extreme importance, because on it depends the good or the potential harm which he may do.

However, nothing but good can come from the frank and open discussion of the matter. If our present practice is wrong the sooner we correct it the better; if it is right—and we are sure that we are on the right track—the more widely it is known and practised by the profession the more lives shall we save, and with so much the more confidence shall we advise and practise these methods. I

venture to suggest that we may safely start with the following postulates:

1. X radiation as at present practised will relieve and sometimes cure certain cases of malignant disease.
2. The doses are now sufficiently standardized for us to understand approximately what we are giving.
3. In the light of this knowledge up to the present date we can rely on the opinion of the recognized authorities on the subject for a candid statement on what we should do in certain common and well-defined classes of cases. I assume, of course, that all have first received, if possible, suitable surgical treatment.

It is not surprising if all authorities are not agreed on the actual details of dosage for all conditions, for are there not many other therapeutic agents of much greater age in which no uniformity of dosage has or can be established? It is doubtful if this will ever be possible. The reaction of the tissues to a stimulus or reagent must differ in individual cases, whether that stimulus be a radiation or arsenic or any other of the therapeutic agents at our disposal. We should, however, be wrong for this reason to refuse to use them.

I cannot help feeling that a frank statement of what we are doing, how we do it, and the results we obtain in the prophylactic and curative treatment of cancer of the breast will do a great deal of good, will save these methods from unmerited disrepute, and will fortify us in continuing what we believe to be useful work. I refer to cancer of the breast because it is in this connexion that Mr. Sampson Handley initiated the discussion, because these cases form a very large proportion of those whom we treat, and lastly, because we are here dealing with a superficial organ in which the loss in penetrating the tissues is smaller than in the case of more deeply seated tumours. For some considerable time—at the instigation of Mr. Sampson Handley—I have been treating these cases in connexion with my general practice, because it was only by doing so myself that most of them were able to obtain the treatment.

The method which I use, wherever practicable, is that recommended by Dr. R. Knox on pp. 461-465 of vol. ii of his standard work on *Radiology and Radio-therapeutics*. I have also carefully watched the methods of treatment carried out under Dr. Salmond at University College Hospital, under Dr. Knox at King's College Hospital, and also, prior to his death, under the late Dr. G. R. Lyster, who was firmly convinced that in radiation lay the hope of the future for the cure of these cases.

Dr. R. Morton's letter of January 29th seems to me to do two things. First, it holds out, with some authority, a promise of a cure in the future; and, secondly, it casts an aspersion on our present methods.

The treatment we now give is with tubes having an equivalent spark gap of not more than 9 in., and by the use of aluminium filters of certainly not more than 6 mm.

It is agreed that the type of radiation necessary to deal with deeply-seated organs is a more penetrating one than that required in treating a superficial organ like the breast. Is it necessary in these cases to use a tube with an equivalent spark gap of 16 in.? At any rate, we do not at present possess them in this country. I write as a general practitioner determined to advise, and as far as possible give, the best treatment obtainable for this condition, and in doing so I believe I speak for a large number of practitioners who have the same object in view.

I appeal to the authorities on this subject to state their views on our present methods. We all wish to have our practice confirmed or condemned, or, better still, brought to perfection in this country as soon as possible, and we believe that by the careful thought and practice of British radiologists this object will be consummated.—I am, etc.,

J. W. JAMES WILLCOX, M.B.Lond.
Glastonbury, Feb. 7th.

THE DROOPING SHOULDER SIGN OF PHTHISIS.

SIR,—I was much interested in the remarks by Dr. W. C. Rivers, in your issue of January 22nd, on the drooping shoulder sign of phthisis, but in stating that this sign is not mentioned in any British textbook Dr. Rivers is in error.

The appearances to which he refers are fully described on pages 65-66 in Dr. Halliday Sutherland's *Pulmonary Tuberculosis in General Practice* (Cassell and Co., 1916).—I am, etc.,

London, S.W., Jan. 26th.

W. J. HOYTEN, M.D.

DEXTROSE IN CARDIAC FAILURE.

SIR,—I can corroborate Dr. Scott MacGregor's recommendation (January 29th, p. 158) to give sugar an extended trial in cases of cardiac failure.

In 1913 I published a case in the *Lancet* (vol. i, p. 1092) which is quoted in Martindale's *Extra Pharmacopoeia* (1915) as follows:

"Life saving by sugar: 8 oz. during twenty-four hours in a case of a woman of 77 with heart disease, where digitalis and digitalin had no effect. Continued some weeks in slightly less amount. Strength slowly regained."

I frequently put my bad heart cases in the Hull Royal Infirmary on sugar in some form—often dissolved lump sugar—as well as bad cases of pneumonia—with good results.

The members of the sugar group of carbohydrates form an easily assimilated food, which sustains and increases the power and endurance of all varieties of muscle fibres; and some form of sugar is always at hand in any household.—I am, etc.,

STANLEY E. DENYER, C.M.G.,
M.D.Camb., F.R.C.S.Eng.

Hull, Feb. 3rd.

THE NAVAL MEDICAL SERVICE.

SIR,—In the *JOURNAL* of January 29th "Surgeon Commander R.N." passes, in a spirit of unctuous rectitude, rather severe strictures on his colleagues. That these charges are ill deserved, and, further, that they are not the cause of the present lamentable condition of the Naval Medical Service, we hope to make clear.

He states that a class of man is attracted to the service who is no use either in or out of the service. We frankly disbelieve this, as until recent years the competition to enter into this branch was about 2 to 1, the selected candidates being mostly highly trained, many of them prizemen, and many ex-house-surgeons and ex-house-physicians. There has been a great exodus of these good young men during the past two years, and if the Admiralty would only permit it, there would be a still further reduction. They are retained in the service, not by any hope of advancement—they have less than a 1 in 20 chance of promotion to surgeon captain—not by the prospect of a "life of leisure and retirement at age 50 with a nice pension of £600," but by the force of the Naval Discipline Act; those who wish to leave are not allowed to. Further, it is remarkable to how very few temporary surgeons, who saw the navy from within, these alluring prospects appealed, and now the Admiralty cannot even get as candidates those whom your correspondent refers to as "idlers and grumblers" and "of no use either in or out of the service."

He asks, What has the average naval surgeon done for the service? Our reply is that he has rendered loyal and honest service in return for emoluments much below the market rate. Contrary to "Surgeon Commander's" statement, the Health of the Navy returns show a progressive decline in the amount of preventable sickness. We have yet to learn of any naval medical scandals during the late war. The naval doctor does not work in the limelight, and the merest glance at the current *Navy List* will show the meagre list of humble O.B.E.'s with which officialdom has recognized his work.

In reply to the painful comparison with the R.A.M.C., we would say that so long as the combination of pay, allowances, and other pecuniary advantages exceeds ours, so long will a justifiable grievance remain, and so long will the other service have first choice of those candidates who wish to enter the "Services." If we must not reasonably compare ourselves with them, with whom, we ask, should we seek comparison?

One can remember the days when the R.A.M.C. did not stand on its present pinnacle of efficiency. It dates its swift rise to fame from the day that it began to "run its own show." There may be some hope for the Naval Medical Service when the Medical Director-General is allowed to become more than a mere figurehead, whose function it is to make occasional recommendations to the Board in whose unprofessional hands the real destinies of the Medical Branch at present lie.

The lack of clinical material in ships is admitted, but do the Admiralty try to obviate this defect by sending medical officers awaiting employment to naval hospitals where there is no lack of good cases, and much really good work

is done? No; they are put on unemployment pay instead. It is, we think, obvious that your correspondent can have had little experience of the work done in naval hospitals—work which compares favourably in quantity and quality with either that of the army or of civilian practice.

Your correspondent thinks that it is high time to put an end to grumbling, and recommends work in lieu, remarking that as the labourer is worthy of his hire so would we have gained the recognition, status, pay, and honours deserved. We might reasonably assume that when the medical officer, by much good service and careful selection, attains to the rank of surgeon rear admiral, he has already attained some distinction, and as such is entitled to generous treatment, but it is common knowledge that his emoluments are in no way adequate, without considerable private means, to enable him to live as he is generally expected to live. When an executive officer attains this high rank a benevolent Admiralty makes the possession of private means unnecessary by the provision of very handsome allowances. Few of us can afford to be so altruistic as to view these matters with the equanimity of your correspondent, nor do we consider that the rewards of our very senior officers are now such as to attract the best men. It is therefore frivolous to speak of the prominence we give to these grave inequalities in treatment of senior officers as "grumbling about status."

It is the merest truism to say that a medical officer's personal status is what he makes it. The medical officer who is his captain's personal friend and confidential adviser is the rule and not the exception, and in this way he does much good work for the service which your correspondent has overlooked. The differentiation in official status is sufficiently shown by the comparison quoted above.

So much for destructive criticism. Of constructive suggestions for improvement of the branch we know there is no lack.—We are, etc.,

Feb. 1st.

TWELVE MEDICAL OFFICERS ROYAL NAVY.

SIR,—I cannot allow the attack on his own branch by one who signs himself "Surgeon Commander" to pass without a reply.

He asks, "What has the average naval surgeon done for the service?" In many cases during the late war he died for it. Possibly in this act your correspondent might admit that the naval medical officer "stood on his own merits." Your correspondent has apparently never read the *Naval Medical Journal*. Since its beginning in 1915 this journal has been a revelation of the extraordinarily good work that naval medical officers are doing both in preventive and other branches of medicine and surgery. In it there are many excellent articles written by men often in isolated ships on distant stations showing the resource and skill by which they extemporized apparatus for laboratory or other work on board ship. The journal alone is a complete refutation of your correspondent's ignorant charges. If naval medical officers had been such as he describes, there would never have been such a journal.

The health of the Grand Fleet during the war, and the records of the treatment of the sick and wounded all over the world, are a sufficient testimony that the naval doctor knew his duty and his job, and did both. There has never been a word of hostile criticism of the treatment of all those thousands of sick and wounded during the war.

To our poor branch that gets all the kicks and none of the halfpence this fact alone is ample justification. In his last paragraph your correspondent infers that the Naval Medical Service is not "a worthy unit of the great service to which we belong." To this I can only reply that if every other branch had been as well equipped and ready for war as the medical, the war would probably have been over considerably earlier.—I am, etc.,

January 31st.

ANOTHER SURGEON COMMANDER.

*** We have received other letters to much the same effect.

AGE AND PENSIONS.

SIR,—Two propositions of the Pensions Ministry are having the effect of disfranchising very large numbers of old soldiers from pensions:

1. In disease disability, not due to but aggravated by service, the pension ceases when the "aggravation" is said to have "passed away."

2. Many disease disabilities of elderly soldiers are said to be "due to age" and not to service; such disabilities, being due to age, cannot be "aggravated by service," and in either case are ruled to be not pensionable.

The fallacy of these propositions requires demonstration. First, as to causation of disease disabilities, the originating causes of every disease are multiple; all diseases are the resultant of innumerable causes. Military service is itself a multiple cause. When a disease is said to be "attributable to" or "aggravated by" military service, the admission of this particular element of causation, by the Ministry's own rules entitles a soldier to pension for the full disability, whatever be its other contributing causes.

The disease or disability resulting from these multiple causes consists of two aspects, functional and organic: (a) a physiological defect of vital reaction to environment and strain; and (b) a pathological material change in the tissues. On the upward curve of life, while the *vis vivendi* is potent—up to the age of 35 or 40—recovery may be complete, the residual defect of vital reaction and the residual tissue change being inconsiderable; no appreciable "disability" remains. On the downward curve of life, when the *vis mortis immanensis* is increasingly potent—after 35 or 40—the residual defect, both in function and in tissue change, usually remains substantial, and cannot "pass away." They render the man increasingly liable to microbial invasions, and impair his general economic efficiency and his reactions to all strains.

The "physical picture" is quite unreliable in measuring the organic disease disabilities of elderly soldiers. By direction of the Ministry's assessors, disabilities are at present assessed by the medical boards mainly, often exclusively, on the "physical picture" recorded by the Board, although the *Manual* clearly directs that all the factors bearing upon the degree of disability are to be taken into account. Experience increasingly shows that in elderly pensioners with chronic disabilities a physical examination gives at best but a few bald positive or negative signs, "a picture" which cannot in itself measure that impairment of general function which constitutes the economic disability of the pensioner in earning his livelihood. The chronic disabilities from which these elderly pensioners suffer are, in the nature of the case, usually of long standing and more or less incurable, liable to more and more frequent recurrence and accentuation as years go on. The illness may "pass away" temporarily, but only in appearance, for each recurrence leaves an increased histological tissue change in the organs affected (not usually verifiable by a physical examination) and an increased tendency to recur. In men on the downward incline of life these consequences cannot in any true or lasting sense "pass away"; on the contrary, they are bound to get worse with time. The actual assessment of these chronic cases is difficult for the following reason:

They cannot justly be assessed by any abstract "comparison of the disabled man with an average healthy man of his age," as laid down by the Ministry. There is no such thing as "an average healthy man of 60"; the healthy men of 60 are a very minute fraction of the sum total of men of 60 surviving at all. There is no average standard of physical condition in elderly men of any age. Truly considered, they are merely the tougher constitutions surviving—and the toughest constitutions may be the most disabled—out of the far greater age-group of their year of birth.

The only standard of any value by which the economic disabilities of elderly men can be measured is the age factor, which has always been ignored or misunderstood or perverted by the Ministry. These disabilities are intimately bound up with the age factor, and the just assessment of elderly soldiers requires that an age factor should in all cases be added to the purely "physical comparison" assessment.

The distinction drawn between cases of disease disability directly attributable to service, and those assumed to have pre-existed before enlistment and to have been "only" aggravated by service, is in many instances artificial and hypothetical. Even when there is proof of pre-war disease, we have usually no evidence at all of the degree of disability on enlistment. When, therefore, after or on demobilization, a case is accepted as "aggravated by service," the pre-war part of the whole present disability has to be assessed by guesswork, several years after the date under assessment, the whole effect of military service intervening. These guesses obviously are variable and of very little value; the very basis of this disfranchisement

of these older soldiers has no true foundation either of record, of science, or of fact.

The only use the Ministry has made of the age factor is a perverse and unscientific one. In order to dispose finally of the whole age question it has laid down the following propositions:

1. "We are not here to assess disabilities attributable to age." "We are not distributing old-age pensions."
2. "Disabilities attributable to age cannot be attributable to service."
3. "Therefore the disabilities of a soldier attributable to, or aggravated by age, are not pensionable."

But age is not in itself a *cause* of anything, so that it cannot either be a cause of disability or exclude any cause of disability, such as service, from acceptance. Age is an approximate measure of innumerable chronic disabilities, whose causes are the same multiple causes which produce the disabilities of all ages. As age advances the tissue changes resulting from disease causes in general (including military service as a cause) become accumulated, and the defect of vital reaction to environment becomes aggrandized, but age remains simply the measure of accumulation, not the cause of the accumulated organic and functional disability. Age in itself is a relative term, a mental concept; considered as a measure of time, a measure of man's life-span, it cannot *cause* disability. We speak of "age-disability" only as a convenient figure of speech, as a concurrent measure of accumulated disability. The perversion of this figure into the formula or belief that "age is a cause of disability" is muddleheaded and unscientific.

In practice the disabilities of older soldiers, though very real in economic effect (to compensate for which is the true purpose of disability pensions), are often difficult to define in the terms of disease. The truth is old age is a disability, which may be and usually is aggravated by service, and that aggravation cannot pass away. The assessing branch of the Ministry appears to have been overweighted by the difficult decisions required of it in the shortest space of time. Its incorrect premiss disfranchises elderly soldiers from the benefit of the Royal Warrant, which (correctly applied) was intended by Parliament to safeguard the interests of all soldiers, old or young, injured by their service in the army, and not least those who served in their old age.—I am, etc.,

January 28th.

A.T.S.

BRITISH AID FOR RUSSIAN MEN OF LETTERS AND SCIENCE.

SIR,—At the beginning of this year you published an appeal for funds to enable a certain number of scientific and literary publications to be sent to the House of Science and House of Literature in Petrograd, where the remnant of the intellectual life of Russia is mostly congregated. The British Committee for Aiding Men of Letters and Science in that country has assured itself that such publications will reach their destination, and has made arrangements for their transmission. There are probably many authors who would be willing to send copies of their works in the form of excerpts or otherwise to Russian workers who have been cut off from the outside world since the revolution. The British Committee will be glad to receive any such books or papers of a non-political type and to send them to Petrograd. It cannot guarantee delivery to individuals, but it can ensure that publications will reach the Houses of Literature and Science. Parcels for transmission should be addressed to us, care of Wm. Dawson and Sons, Ltd., Continental Department, Rolls Buildings, Fetter Lane, E.C.—I am, etc.,

L. F. SCHUSTER,
Secretary.

British Science Guild Offices,
6, John Street, Adelphi, W.C.2.
January 26th.

By the will of the late Mr. William Roper Teage of Dartmouth, who left net personalty of £78,487, the residue of his property is left to charitable institutions, including ten parts to the South Devon and East Cornwall Hospital; four parts each to the Dartmouth Cottage Hospital and King Edward's Hospital Fund; two parts each to Guy's Hospital, the London Hospital, and the Poplar Hospital; and one part each to the Middlesex Hospital, the Cancer Investigation Department of Middlesex Hospital, the Royal London Ophthalmic Hospital, and to three special hospitals in Plymouth.

Obituary.

F. H. DAYUS, M.R.C.S., L.R.C.P.,
Forest Gate.

DR. FREDERICK HERBERT DAYUS, Chairman of the West Ham Insurance Committee, died at Cumberland Lodge, Forest Gate, London, E., on January 26th. After studying at St. Mary's Hospital, he obtained the conjoint diploma in 1893. He was subsequently appointed resident casualty officer at St. Mary's Hospital, and served as resident medical officer to the London Fever Hospital. After a brief period of practice in the county of Durham, he established himself in West Ham, where he speedily obtained an extensive practice. He was always an enthusiastic supporter of the British Medical Association, never wearying of pointing out that it was the only possible organization for the profession. He joined the executive of the Stratford Division in 1907, and retained his seat thereafter. He was vice-chairman of the Division during the years 1911-12, while the National Insurance Act was under discussion, and was frequently called upon to preside over the large meetings which gathered during those troubled times. He was a member of the West Ham Panel Committee since its formation, and its first chairman. He was elected by the practitioners of West Ham as their first representative on the West Ham Insurance Committee, and his annual re-election became a matter of course. He served as chairman of the Sanatorium Benefit Subcommittee, and was a member of the Medical Benefit Subcommittee from the beginning. In 1920, having served a year as vice-chairman, he was unanimously elected chairman of the West Ham Insurance Committee, and this office he held at the time of his death. He thus shared with Dr. Dain of Birmingham the distinction of being one of the two medical chairmen of Insurance Committees. In this office he excelled; his knowledge of men, his tactful and conciliatory bearing, and the firmness and decision of his rulings made him almost ideal, and his assiduous attendance at subcommittees kept him fully conversant with all the committee business. Dr. Dayus was also a member of the local War Pensions Committee, and honorary medical adviser to the Stratford Day Nursery and to the Mothers Welcome of the Trinity Oxford City Mission.

Early in life he became a Freemason, and entering into it with his characteristic zeal, he rose to high office. In the midst of these multitudinous activities his advice and assistance were always at the disposal of those that sought them; no call upon him was ever made in vain, and his death at the early age of 52, in the full tide of his career, adds one more to the long line of medical men who have paid for their devotion to the public with their lives. The funeral service, which took place at West Ham Parish Church, within a few yards of the place where he had carried on his life's work, was the occasion of a remarkable demonstration of feeling. The large building was completely filled by a gathering fully representative of all the numerous bodies with which he was connected, together with friends and patients, but far more impressive was the scene outside, where thousands of people packed the streets and waited patiently in a dreary drizzle throughout the service to see the last of him who had served them so well.

We regret to announce that Mr. HENRY BARTON OWENS, M.R.C.S. Eng., L.R.C.P. Lond., of Paulerspury, Towcester, Northants, died on January 15th, after a week's illness, of acute septicaemia, in his 32nd year. Born at Long Stratton, Norfolk, he was the second son of Charles A. O. Owens, M.D., J.P., who has practised there for nearly fifty years. On leaving the London Hospital he became house-surgeon at Poplar Hospital. At the outbreak of the war he obtained a temporary commission in the R.A.M.C., dated August 8th, 1914, and was posted to the 3rd Cavalry Field Ambulance at the Curragh. He went over as with the first expeditionary force in the 1st Cavalry Division, and was very soon attached to the 4th (Royal Irish) Dragoon Guards. Among the many battles he was engaged in were the retreat from Mons, Le Cateau, Marne, Aisne, Ypres, Somme, Amiens, and in the final advance. He was a long time with the 57th Field Ambulance, 19th Division, taking his turn as medical officer to several battalions, including the Royal North

Launce-hires and also the Royal Engineers. He was twice mentioned in dispatches. His name appears in Colonel Berton's book, *The R.I.M.C. in the Great War*. One of his comrades with whom he was closely connected during the war writes: "Many a time have I been cheered by his company and courage in France, where his gallantry and devotion to duty were so inadequately rewarded, though fully appreciated by his real friends." He was a keen sportsman, never happier than when following hounds, and was well known as a riding true and straight with several packs in Norfolk and co. Tipperary. He was gifted with a facile pencil, many of his sketches and water colours done in France during the war possessing additional interest in the fact that some of the places represented no longer exist. He married, in July, 1920, Winifred Mary, daughter of the late Henry Mandeville, R.N., of Anner Castle, Clonmel, co. Tipperary. In October he commenced practice at Paulerspury, where he died.

WE regret to announce the death of Dr. PATRICK CHARLES GORHAM, of Clifden, Connemara, who for nearly fifty years had been connected with the medical life of West Galway. Dr. Gorham was educated at Queen's College, Galway, and at Dublin and Edinburgh, qualifying L.R.C.P., L.R.C.S. Edin. in 1874. He was for forty years medical officer of health of Roundstone and Clifden districts, and medical officer to the Clifden workhouse and fever hospital, but failing health caused him a few years ago to accept superannuation. A colleague writes: For a considerable time it was known that Dr. Gorham was in failing health, but when the news came that he had passed away the expressions of regret and sorrow were many, and the funeral cortege was the largest seen in Connemara in living memory. Those who were admitted to his friendship, and his poor patients in particular, held for him an especial regard and love. Among the visitors who made Connemara their headquarters for fishing, shooting, and other sports, Dr. Gorham was a special favourite, and he numbered among his friends Lord Randolph Churchill, Mr. George Wyndham, and a host of other well known people. When the Poor Law Association wished to promote a measure of superannuation for the Poor Law officers of all grades, they availed themselves of his friendship with Mr. Wyndham by constituting Dr. Gorham their chief spokesman, with the result that the Chief Secretary undertook to forward their interest, but owing to political opposition he was compelled to abandon their case. Dr. "Pat" Gorham in his love for his poor patients and striking example of devotion in the pursuit of his duty has left to his colleagues in the Poor Law medical service an example and an inspiration. In his family of six brothers, of whom two now survive, four selected medicine as their profession.

WE regret to record the death of Dr. PHILIP G. NUNN, at Bournemouth, on January 10th, in his seventy-third year. He received his medical education at St. Bartholomew's Hospital, and took the diplomas of M.R.C.S. in 1871 and L.R.C.P. in 1873. In 1874 he was appointed medical officer of health for Bournemouth, and he continued to hold that post, with the exception of about four years, till he retired in 1911, when he was appointed consulting medical officer of health. During this period the population of Bournemouth rose from 7,000 to over 80,000. Dr. Nunn was consulting surgeon to the Royal Boscombe Hospital and an ex-president of the Dorset and West Hants Branch of the British Medical Association.

Dr. EDWARD J. SPITTA, who died on January 21st, aged 68, received his medical education at St. George's, St. Thomas's and Westminster Hospitals, and obtained the diplomas of L.R.C.P. and M.R.C.S. Eng. in 1874. He was prizeman in anatomy at St. George's Hospital Medical School and held the post of senior demonstrator in anatomy. He joined his father in practice at Clapham in 1874, and retired in 1904, when he removed to Hove. In 1899 he brought out his book on *Photomicrography*, and that on *Microscopy* in 1907. At the request of the British Government he showed, in conjunction with his son, Dr. Harold Spitta, M.V.O., Bacteriologist to the Household of H.M. Queen Alexandra, a series of photomicroscopical exhibits

at the Paris International Exhibition in 1903, when he was awarded the Grand Prix. He was also awarded a gold medal for his exhibits at the exhibition at St. Louis in 1902. On retiring from practice he devoted himself to research work in microscopy and photography, and was the first scientist to produce cinematograph pictures of plants and insect life. Dr. Spitta was a Fellow and Vice-President of the Royal Microscopical Society and was President of the Quekett Microscopical Club in 1904-8. In recent years he was greatly interested in wireless telegraphy, and at the time of his death was engaged on experiments in wireless telephony.

His death has occurred, at the early age of 25, of Dr. ROBERT DAVID JONES of Penrhyneddwrach, Merioneth, as the result of a railway accident. He was the son of Dr. J. R. Jones of Penrhyneddwrach, and received his medical education at the University of Liverpool and St. Bartholomew's Hospital. He was awarded the Torr gold medal in anatomy at the University of Liverpool in 1914-15, qualifying M.R.C.S., L.R.C.P. in 1918. He had been senior house surgeon at St. Bartholomew's Hospital, and had served as captain in the Royal Air Force Medical Service. Dr. Jones only returned a few days before from a short trip to India.

WE regret to record the death of Dr. GEORGE NISBET, of Quinton House, Kirkby-in-Ashfield, Notts, which took place, after a long illness, on January 16th. Dr. Nisbet received his medical education at Edinburgh University, and qualified in 1904. A well known and popular practitioner, he took a great interest in the work of the British Medical Association, and acted as local secretary in the Kirkby district of Nottinghamshire.

Medico-Legal.

ACTION AGAINST A MEDICAL OFFICER OF HEALTH.
IN the JOURNAL of July 31st, 1920, p. 182, an account was given of the action for damages for libel brought by Mrs. Mabel Copeland against Dr. Thomas Orr, the medical officer of health of the borough of Ealing. The case was heard in the King's Bench Division on July 15th before Mr. Justice Roche and a common jury. The plaintiff was a lady sanitary inspector in the service of the Ealing Town Council. The jury found £25 damages in favour of the plaintiff, but the judge postponed the entering of judgement pending legal argument. Four days later, in the same court, Mr. Hemmende, K.C., counsel for the defendant, moved that judgement be entered for the defendant on the ground that there was no evidence of malice. Mr. Justice Roche, in the course of an argument by counsel on both sides, used the following words: "It is not for me to set the jury's verdict aside as being an unreasonable verdict, but I am entitled to say that I am very dissatisfied with it. It is difficult, however, to say that there was no evidence which could be submitted to the jury." Judgement was therefore entered for the plaintiff for £25, and the defendant entered an appeal.

In the Court of Appeal, on February 2nd, before Lord Justice Bankes, Warrington, and Atkin, Dr. Orr appealed on the two grounds that the judge was wrong in not withdrawing the case from the jury, because there was no evidence of malice to go to them, and, alternatively, that even if there was evidence of malice the verdict was against the weight of the evidence. Mr. Bell Hart, instructed by the Town Clerk of Ealing, said that Dr. Orr took up his duties as medical officer in August, 1915, and the respondent's case was that from the first he adopted a harsh attitude towards her, often complaining of her work and requesting her to be more methodical and to conform to certain new regulations he had made; her health thereby became affected. It was not suggested that Dr. Orr made any sort of report detrimental to the plaintiff before April 10th, 1917, but on that date he was asked by the council to report on her work, and in response he spoke the words which the respondent maintained were slanderous. Counsel then went into the detailed evidence given at the trial, and in support of the appeal he laid stress on the fact that Mr. Justice Roche had himself expressed dissatisfaction with the verdict.

Lord Justice Bankes, giving judgement, said the amount of damages awarded was very small, but the principle underlying the verdict was very important, because were the verdict allowed to stand the impression might be produced that if any person did not get on well with a superior officer, and was necessarily taken to task by that officer for not performing his or her duties to the officer's satisfaction, he or she would be compelled to make a report on the officer, and that such report would be taken as evidence that he had a grudge against the officer. In this case there was no evidence that Dr. Orr acted maliciously on what was admitted to be a privileged occasion, or that he had been

animated by ill-will at all. After referring to the relations between Dr. Orr and Mrs. Copeland, his Lordship said it appeared to him that so far from the doctor having shown malice, he was forbearing and was anxious to take a step which might not do the lady harm. Referring to a letter sent by the respondent's sister to Dr. Orr, his Lordship said it raised a grave matter, because it suggested that, owing to the doctor's attitude, the respondent had so suffered in health that she could not perform her duties. It was incumbent upon the doctor when he received that letter to bring the matter before his superiors, and he did so on April 30th. That was not done voluntarily, but he was forced into it; and it was not evidence of malice or of anything but acting under a pure sense of duty. In his Lordship's opinion the appeal must be allowed, the judgement below set aside, and judgement entered for the appellant (Dr. Orr) with costs in the Court of Appeal and below. Lords Justices Warrington and Atkin concurred; the latter added that in his opinion everything that took place was consistent with the appellant doing his duty. Even if there had been any feeling of hostility before the report was communicated it did not justify the finding of express malice.

The appeal was accordingly allowed, the judgement below set aside, and judgement entered for Dr. Orr, with costs of the trial and appeal.

Universities and Colleges.

UNIVERSITY OF LONDON.

A MEETING of the Senate was held on January 19th. The Prince of Wales has consented to accept the honorary degrees of Master of Commerce and Doctor of Science, which will be conferred on Presentation Day in May.

The Senate expressed gratification at the anonymous donation of £20,000 made to the Middlesex Hospital Medical School for the endowment thereof of the University Chair of Physiology. It was resolved to institute a University Chair of Embryology at University College and a University Chair of Physics at Bedford College. Applications for the latter post (£800 per annum) to be sent to the Academic Registrar by April 16th.

It was resolved that the regulations for the M.D. examination (Branch III. Mental Diseases and Psychology, Red Book 1920-21, p. 264, and Blue Book 1920, p. 247) be amended by the addition of the following at the end of Branch III:

In and after the examination to be held in December, 1922, the Regulations for Branch III will be as follows:

Branch III—Psychological Medicine.—Two papers in Mental Diseases and Mental Deficiency. One paper in Psychology. One paper in Neurology, which shall include the anatomy and physiology of the nervous system. An essay on one of two subjects in mental diseases or a case for commentary in mental diseases. A clinical examination.

The necessary consequential changes in the title of the M.D. examination (Branch III) are to be made in the regulations.

Sir James Barr has been reappointed Chancellor's representative on the Court of the University of Liverpool, and Dr. Russell Wells has been reappointed the representative of the University on the General Medical Council.

The University Medal in Branch VI (Tropical Medicine) of the M.D. examination, December, 1920, has been awarded to E. S. Phipson (University of Birmingham), and the University Medal in Branch I (Surgery) of the M.S. examination, December, 1920, to R. L. Horton (University College Hospital).

Applications for grants from the Dixon Fund for assisting scientific investigations must be received by the Senate between April 1st and May 15th, 1921. Applications for the University studentship in physiology must be received by the Principal Officer by May 31st. The studentship (value of £50 for one year) is tenable in a physiological laboratory of the University or a school thereof. Full regulations as to award can be obtained on application.

Essays and dissertations on hyperthyroidism and its surgical treatment, for the Rogers Prize (value £100), must reach the Vice-Chancellor by April 30th. It is open to all persons whose names appear on the *Medical Register*.

Applications for the University chair of anatomy, tenable at St. Bartholomew's Hospital Medical School (salary £900 per annum), must be received by the Academic Registrar at the University by April 14th.

UNIVERSITY OF SHEFFIELD.

THE following candidates have been approved at the examinations indicated:

D.P.H.—W. J. Fordham, G. G. Marshall.
THIRD M.B., CH.B.—Annie D. Sykes.

UNIVERSITY OF BIRMINGHAM.

THE Council of the University, in its report to be presented to the forthcoming meeting of the Court of Governors, states that so far the response to the university's appeal for £500,000 has reached £280,444, of which £135,417 has been specially allocated by the donors, leaving £145,027 for general purposes.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

AN ordinary Committee of the Royal College of Physicians of London was held on February 3rd, when the President, Sir Norman Moore, was in the chair.

Licences to practise physic were granted to the following eighty-three candidates who had passed the necessary examinations:

*Doris E. Alcock, H. E. Alexander, G. W. Almeyda, C. H. Andrews, H. N. Andrews, Kathleen Ardell, O. A. Baker, W. F. Barnes, H. E. Beasley, Margaret G. Best, L. M. Billingham, I. Main, C. H. Bracewell, J. L. McK. Brown, R. Buddle, C. L. C. Burns, A. Y. Cantin, *Dorothy S. Chamberlain, L. C. F. Chervens, F. Christian, *Ivy Collier, F. P. de Caux, A. H. G. Down, A. G. Duncan, T. A. Eccles, R. T. Edwards, H. Franklyn, O. P. Gallegos, G. I. Griffiths, W. R. W. Haight, H. W. Hammond, *Katharine M. Harbord, H. J. H. Hendley, T. B. Hodgson, S. H. G. Humphrey, A. Y. Ibrahim, J. G. Johnstone, H. C. V. Joy, A. N. Kingsbury, F. G. Latham, *Anna G. M. Lewis, C. J. Lewis, C. A. Lindup, *Kathleen M. B. McArthur, H. McKenzie, *Elizabeth Matthai, A. Mikhail, G. S. Mitchell, W. P. Newman, Helen O'Brien, F. B. Oliver, S. Orchard, T. L. Ormerod, *Tressia L. Pires, *Olive G. Potter, C. S. C. France, I. M. Rattray, P. L. Richardson, O. A. L. Roberts, A. el R. Roushdy, G. R. A. de M. Rudolf, H. L. Sackett, A. el R. Sami, *Maud Sanderson, R. G. V. Shaw, N. L. Sheorey, E. A. Sparks, H. Spibey, J. A. Stevens, R. N. L. Symes, A. H. Talaat, K. H. Tallerman, H. E. Thomas, J. S. Thomas, N. G. Thomson, H. M. Toop, G. D. C. Tracy, T. W. Turner, *Madeline H. J. Umpleby, Gladys M. Wauchope, *May G. Williams, H. N. Witham, F. W. Zaglana.

*Under the Medical Act, 1876.

A letter was received from the Voluntary Hospital Committee appointed by the Ministry of Health, with Lord Cave as chairman, to inquire into the financial position of the voluntary hospitals, inviting the College to present evidence. A reply was drafted pointing out the importance of the voluntary principle in relation to the interests of the sick, medical education, and the increase of knowledge. The President and Censors were appointed as representatives of the College if evidence were desired on these points.

A report from the Committee of Management on the Conjoint Examination in Midwifery and Diseases of Women was discussed and referred back for further recommendations.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Arris and Gale Lectures.

AN Arris and Gale Lecture, on the function of the kidneys in enlargement of the prostate gland, will be delivered in the theatre of the College, Lincoln's Inn Fields, W.C., on Friday, February 18th, at 5 p.m., by Mr. J. F. Dobson, M.S., F.R.C.S.

An Arris and Gale Lecture, on the azygos system of veins in their association with surgical affections, will be delivered in the theatre on Monday, February 21st, at 5 p.m., by Professor J. Howell Evans, M.D., M.Ch., F.R.C.S.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

Parkin Prize.

IN terms of the bequest made to the College by the late Dr John Parkin, a prize, value £100, is offered for the best essay on certain subjects connected with medicine. The subject of the essay for the present period is, in terms of the deed—

"On the effects of volcanic action in the production of epidemic diseases in the animal and in the vegetable creation, and in the production of hurricanes and abnormal atmospheric vicissitudes."

The prize is open to competitors of all nations. Essays intended for competition, which must be written in the English language, must be received by the Secretary not later than December 31st, 1921. Each essay must bear a motto, and be accompanied by a sealed envelope bearing the same motto outside, and the author's name inside. The successful candidate must publish his essay at his own expense, and present a printed copy of it to the College within three months after the adjudication of the prize.

The Services.

BIRMINGHAM TERRITORIAL DINNER.

THE annual supper and smoking concert of the Royal Army Medical Corps (Territorial Units) of Birmingham was held at the White Horse Hotel on January 28th, with Lieut.-Colonel C. H. Howkins, C.B.E., D.S.O., T.D., in the chair. The A.D.M.S. of the Division, Colonel L. J. Blandford, A.M.S., C.B.E., T.D., was present, and the chairman was supported by Lieut.-Colonel R. A. Broderick, D.S.O., M.C., and Lieut.-Colonel H. F. W. Boedicker, R.A.M.C.T.F.

The Chairman in a short speech said the great strides that had been made in recruiting for the units since the New Year and the indication there was that these units would shortly be at full peace strength. He also pointed out that the difficulties in regard to the establishment and enlistment of transport personnel having been settled, this important branch of the field ambulances should soon be in full swing. Lieut.-Colonel Broderick remarked on the great hopes there were of acquiring the use of a suitable drill hall at Sutton Coldfield, thereby creating in that district a section of the 2nd Field Ambulance, as obtained in pre-war days. Colonel Blandford expressed his appreciation of the progress made by the units in recruiting, and hoped that the social side of the Territorial Army would be kept up to the old traditions. It was a generally accepted fact that the transport sections would be just the same as in pre-war days, except that "R.A.S.C." would be substituted for "R.A.M.C." in the shoulder title of the personnel. Major L. Ball, M.C., on behalf of Lieut.-Colonel Boedicker, expressed his pleasure in being able to announce that a band was

in progress of formation for these units. This would no doubt be a splendid means of providing congenial entertainment for the members, both at headquarters and in camp, and would also prove a big incentive to recruiting.

About 100 members were present, and a strong programme was provided, which was thoroughly appreciated by all present.

HONOURS.

FOREIGN DECORATIONS.

THE following decorations have been conferred by the King of the Belgians for distinguished services rendered during the course of the campaign:

Ordre de Leopold—Chevalier: Lieut.-Colonel Robert Tilbury Brown, C.M.G., D.S.O., R.A.M.C.; Lieut.-Colonel Edmund Philip Hewitt, R.A.M.C.

Officer: Colonel William Coates, C.B.E., V.D., Lieut.-Colonel James Fitzgerald Martin, a temporary Captain George Arthur

General Sir T. H. John G. Goodwin, temporary Major Harry Compton Parsons, T.D., R.A.M.C.T.F. (honorary Lieut.-Colonel N.Z.M.C. Reserve of Officers); Brevet Colonel Sir Edward S. Worthington, K.C.V.O., C.B., C.M.G., R.A.M.C.; Brevet Lieut.-Colonel Andrew Rae Wright, D.S.O., R.A.M.C.

DEATHS IN THE SERVICES.

COLONEL MATTHEW DANIEL O'CONNELL, A.M.S. (ret.), died at Leeds on January 22nd, aged 75. He was born at Cork on April 5th, 1847, educated at Queen's College, Cork, and graduated M.D. and M.Ch. in the Queen's University, Ireland, in 1869. Entering the army as assistant surgeon on April 1st, 1871, he became colonel on April 10th, 1901, and retired on April 5th, 1907. He served on the North-West Frontier of India in the campaign of 1897-98, receiving the medal with a clasp. He was the author of a work on *Climatic and Age*, 1909.

Lieut.-Colonel Thomas Henry Delany, Indian Medical Service (retired), died on October 10th, 1920, aged 50. He was educated at the Catholic University, Dublin, graduating M.B., B.Ch., and B.A.O. of the Royal University of Ireland in 1895 and M.D. in 1905. He also took the F.R.C.S. (Ire.) in 1905. He entered the I.M.S. on January 23rd, 1893, became lieutenant-colonel in 1917, and retired on January 29th, 1918. He served in the China war of 1900, and received the medal; for most of his service he was employed as a civil surgeon in Bengal.

Major Richard Rutherford, R.A.M.C., died at Cheltenham on January 12th. He was the son of the late Richard Rutherford, F.R.C.V.S., here he graduated as M.B. and Ch. A.M.C. as lieutenant on September 1st, 1914. He served in France in the recent war, and received the 1914 star and the medals.

Medical News.

DR. ALEXANDER F. R. WOLLASTON, who was lately elected to a Fellowship at King's College, Cambridge, has been chosen as medical officer of the forthcoming Mount Everest Expedition. Dr. Wollaston was awarded the Gill Memorial Prize by the Royal Geographical Society in 1914 in recognition of his explorations in the Sudan, Ruwenzori, the Pacific, and Dutch New Guinea.

A REUNION dinner of the staff (medical officers, sisters, and V.A.D.'s) of No. 14 General Hospital (Wimereux) will be held at the Ladies' V.A.D. Club, 28, Cavendish Square, London, W., at 7.30 p.m., on Wednesday, March 16th. Lieut.-General Sir John Goodwin, K.C.B., Director-General A.M.S., will preside. Applications for tickets, price 15s. inclusive, should be made, together with remittance (postal orders, crossed "Holt and Co."), to Miss Sloggett, 6, Bickenhall Mansions, London, W.I.

As there is reason to believe that numbers of imported thermometers are being offered for sale in this country without having been officially tested, the Board of Trade point out that, under the provisions of the Clinical Thermometers Order, 1918, no person may sell, offer for sale, supply or deliver any clinical thermometers which have not been tested, approved, and marked at the National Physical Laboratory. Purchasers should, in their own interests, see that any thermometers offered to them bear the official test mark—namely, a monogram formed with the capital letters N.P.L., followed by two figures denoting the year of test. The above requirements apply to foreign thermometers imported into this country equally with those of British manufacture, but clinical thermometers exported from the United Kingdom need not at present be tested and marked.

A SPECIAL council of governors of the Great Northern Central Hospital will be held on February 16th to consider and, if thought fit, to pass a resolution approving and

giving effect to the recommendation of the Committee of Management for the absorption of the Royal Chest Hospital, City Road.

THE joint meeting of the Röntgen Society with the Institution of Electrical Engineers and the Electro-Therapeutic Section of the Royal Society of Medicine has been postponed until next autumn.

AT the next meeting of the Medico-Psychological Association of Great Britain and Ireland to be held on Thursday, February 24th, 1921, at 11, Chandos Street, Cavendish Square, W.1, at 2.45 p.m., Sir Frederick Mott will read, in conjunction with Dr. Hayao, a paper on the pathology of dementia praecox, especially in relation to the condition of the ovaries.

A MEETING of the Society of Superintendents of Tuberculosis Institutions will be held at 122, Harley Street, at 4 p.m., on Monday, February 14th, when the main business will be the consideration of committee reports on the co-ordination of institution statistics, the training of nurses, and the standards of medical and nursing staffs.

AT a meeting of the Harveian Society on Thursday, February 17th, at 8.30 p.m., in the Town Hall, Harrow Road, Paddington, Dr. William Brown will read a paper on psycho-analysis.

THE different aspects of Einstein's theory of relativity will be described in a series of articles to be published in the special issue of *Nature* on February 17th. The contributions will form an authoritative scientific statement on relativity from various points of view.

COLONEL S. LYLE GUMMINS has vacated the post of Professor of Pathology at the Royal Army Medical College, London, and has assumed duty as Professor of Tuberculosis at University College, Cardiff.

MEMBERS of the Board of Management, the medical staff, and the governors and subscribers of St. Mary's Hospital recently made a presentation—in the form of a cheque—to Mr. Thomas Ryan on his retirement from the secretaryship of the hospital after a tenure of office of more than thirty-three years.

IN a paper read before the Society of Public Analysts on February 2nd Mr. F. W. Smith, B.Sc., stated that after much practical experiment with preparations of various types of squill, the most effective squill rat poison was found to be that prepared in water from an alcoholic extract of the fresh bulb of the red squill (*Scilla maritima*). Salicylic acid could be used as a preservative of this preparation without fear of hydrolyzing the glucoside.

AN institute of biology named after Ramon y Cajal has been established at Madrid. It is to consist of four sections devoted to human and comparative histology, neurology, physiology, and experimental pathology respectively.

SOME months ago Viscount and Viscountess Cowdray presented 20, Cavendish Square, formerly occupied by Mr. Asquith, to the College of Nursing for its headquarters and for a residential club for members of the college. It has been decided that the house shall be exclusively used as a club, but that the garden, having a frontage to Henrietta Street, shall be utilized as a site for the college; to give effect to this Viscountess Cowdray has increased the gift to a total of £100,000. The club-house, it is expected, will be ready by midsummer, but the erection of the college, which will contain offices, classrooms, and fifty bedrooms, will be deferred until building operations become cheaper.

MR. CHARLES J. HEATH, F.R.C.S., has been elected a Companion of the Institute of Marine Engineers.

LIEUT.-COLONEL WILLIAM SCATTERTY, R.A.M.C.(R.), has been appointed a Knight of Grace in the Order of St. John of Jerusalem, and Lieut.-Colonel Frederick S. Lambert, R.A.M.C.(T.F.), an Esquire.

THE second congress of the Italian Society of the History of Medical and Natural Sciences will be held at Bologna in October, 1921, under the presidency of Professor Domenico Maiocchi, when Professor Maiocchi will read a paper on prehistoric surgery, and Professor D. Bardazzi one on the teaching of clinical medicine in the Middle Ages.

DR. DEPIERRIS, Secretary of the Société Française d'oto-rhino-laryngologie and an authority on hydrology, has recently died at Cauterets at the age of 65.

MESSRS. GEORGE AND HENRY WILLS, who contributed large sums towards founding the University of Bristol, have given a further £200,000 to complete the building extension to the university which is being erected at their expense in memory of their father, the late Mr. H. O. Wills, the founder.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Antilogus*.

2. MEDICAL SECRETARY, *Medisecra*, Westland, London; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, *Medisecra*, Westland, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus*, Dublin; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, Edinburgh; telephone, 4361, Central).

QUERIES AND ANSWERS.

BRASS FEVER.

"X. X.," who practises in an industrial district of Scotland, writes: "In the foundry of a works with which I am connected the men suffer from a condition called by them 'brass fever.' Some suffer more than others, but there does not seem to be any natural or acquired immunity. It is presumably due to the fumes arising from the molten alloys. The symptoms are headache, shivering and sensation of cold all over, followed by a feeling of great heat and, after a variable time, by heavy sweats. There is then a feeling of exhaustion and 'soreness all over.' At the end of twenty-four to forty-eight hours convalescence is established and the men resume work, although feeling 'lump.' I should be much obliged if you could refer me to any literature or other source of information on the subject."

* * The malady in question is well known as occurring among the brass pointers in Birmingham. There it is spoken of as "brass founder's ague," a misnomer, for it has no connexion with ague. The malady affects principally newcomers, or men who have been off work for a few days. It only lasts for a few hours, but during that period it is disconcerting. A short account of the illness is to be found in Sir Thomas Oliver's *Diseases of Occupation*, published by Methuen and Co.

INCOME TAX.

"F. L. O." was rightly assessed for two months' profit in 1919 on his own account, and subsequently was in partnership in the same year, but in another place for three months. During that three months his professional expenses exceeded his takings. This is admitted by the taxing authorities, but they do not agree to setting off that loss against the previous profit.

* Section 31 of the Income Tax Act, 1918, provides *inter alia* that "where any person sustains a loss in any . . . profession . . . carried on by him in partnership . . . he may, upon giving notice in writing to the inspector within six months after the end of the year of assessment . . . apply for an adjustment of his liability by reference to the loss and to the aggregate amount of his income. . . ." We have been informed that the period of six months allowed for notice is by tacit concession extended to twelve months, and we suggest that our correspondent "apply" to the inspector and ask to be supplied with a copy of any form of declaration that may be required for a claim under Section 31, Income Tax Act, 1918.

TINNITUS AURIUM.

"M.B." writes from British Guiana, in regard to the query in the JOURNAL of November 6th, 1920, regarding the efficacy or otherwise of vaccine treatment in tinnitus aurium. I should be grateful, as a sufferer myself for some months, for any suggestion that might lead to permanent benefit. The only drug I have found to give definite, if temporary, relief, is quinine, the sulphate or the hydrochloride, but it produced arrhythmia of the heart, and was therefore stopped.

* * Some aural surgeons, we believe, prescribe dilute hydrobromic acid in fairly large doses—say 5j in water thrice daily.

DILATED PUPILS.

DR. W. B. INGLIS POLLOCK (Glasgow) writes in reply to "C. F. R.": I had a man of 29 years of age referred to me in November, 1905, with fully dilated pupils on both sides, of ten months' duration. He gave a history of a sore on the lip, followed by a sore throat, nine years previously. The eye condition was due to nuclear paralysis of the sphincter pupillae muscle, and also partial paralysis of the accommodation. He complained of double vision, but on investigation he was found to have polyopia, due to irregular peripheral astigmatism of the lens. He was ordered mercury and potassium iodide, to be continued for some years. With suitable glasses for distance and for near work the polyopia disappeared. He returned to see me at different times during the intervening years, until in April, 1920, his doctor informed me that he had developed general paralysis and had been sent to an asylum. I would advise "C. F. R." to put his patient on mercury and potassium iodide, even if the cerebro-spinal fluid is negative to the Wassermann test. If there is paralysis of accommodation she will require careful testing for suitable lenses.

LETTERS, NOTES, ETC.

A MEDICAL RESEARCH EXHIBIT.

At the Efficiency Exhibition, now being held at Olympia from February 10th and 25th, the Middlesex Hospital Research Department have a stand showing some of the apparatus and methods of research employed in the ordinary work of a large hospital. In this exhibit are shown, for example, the stages that a piece of tissue goes through from the preliminary fixation in formal saline to the finished section ready for microscopical examination, and at a bench some of the lay assistants of the research departments are seen carrying out routine laboratory methods. Various bacteriological, chemical, and histological processes are demonstrated, and other exhibits include an electrocardiograph, x-ray apparatus and pictures recording drums, a telemicroscope and apparatus for microphotography. In connexion with this exhibit two series of short public lectures are being delivered in the Conference Hall. Dr. Tuck, lecturer on chemistry in the Middlesex Hospital Medical School, deals with chemical research as a foundation stone of medicine, of industrial health, and of pharmacology; and another series is given by Professor W. S. Lazarus Barlow on fluorescence and ultraviolet rays, on x-rays and their uses, and on radium and its rays. The exhibit and the lectures are designed to stimulate public interest in research generally, and in research as applied to medicine in particular.

SUPERNUMERARY NIPPLES.

DR. T. B. SILLITT (Maidenhead) writes. During a recent medical inspection at a secondary school a well formed box of 15 years presented a pair of perfectly developed supernumerary nipples, complete with areolae, about 1½ in. vertically below the site of the normal nipples. He as well as his father has the same anomaly but that his sister is free. In the course of over 52,000 examinations of school children during the past twelve years I do not remember to have met more than one other similar case. I therefore thought it worth recording on account of its rarity and biological significance. It would be interesting to know what happens to supernumerary nipples during adolescence and pregnancy when this condition is found in female.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 38, 39 and 40 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 36 and 37.

THE following appointments of certifying factory surgeons are vacant: Kings Cliffe (Northampton) Mayle Stirling, Monmouth (Monmouth), Stannan (Gloucester).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s	d
Six lines and under	0	9	0
Each additional line	0	1	6
Whole single column (11 lines column)	7	10	0
Half single column	3	15	0
Half page	10	0	0
Whole page	17	0	0

An average line contains six words.

All advertisements by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance if not safeguarded.

Advertisements should be delivered, either by hand to the Editor, 429, Strand, London, not later than the first post on Tuesday, or by recorded publication, and, if not paid for at the time, must be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive postage for letters addressed either in initials or numbers.

205. Pernicious Anaemia in Childhood.

ACCORDING to MENSI (*La Pediatria*, September 1st, 1920) pernicious anaemia is one of the rarest of children's diseases, only four cases (whose ages ranged from 7 months to 7 years) having been observed among 3,029 children under the author's care in a children's hospital. Of 29 cases in children whose ages and sexes are recorded, 14 were under 2 years and 15 above 2 years; 20 were males and 9 females. Apart from syphilis, tuberculosis, and the bothrioccephalus, in the great majority of cases it is impossible to find any causal factor. There is a plastic form, which is by far the commonest, as well as an aplastic form; intermediate or hypoplastic forms have also been described. The prognosis is most unfavourable: of 20 cases 16 died, in 3 the issue was not recorded, and 1 (Mensi's fourth case) was still alive at the time of writing. Treatment appears almost valueless.

206. Calomel Injections in an Aqueous Excipient.

A GOOD deal of pain sometimes follows calomel injections when given in oily emulsions; with a view to avoiding this PORCELLI (*Riv. Osped.*, November 30th, 1920) has been using an aqueous solution prepared by Professor Mazza and containing no gum arabic. The preparation gives a perfect emulsion with a light shaking and without boiling. Low temperatures do not materially affect the fluidity of the excipient. Under the microscope the emulsion is seen to be made up of very minute shining crystals of a globular or dumb-bell shape, uniformly distributed and without any tendency to form clumps. After some preliminary trials on animals, the author used it clinically in men and women, with good results. In 78 per cent. of the cases there was no pain at all; in 14 per cent. very slight and temporary pain came on twelve to twenty-four hours after injection; in 8 per cent. the pain was more marked, but always bearable. No abscess formation occurred. The therapeutic effects were excellent.

207. Treatment of Intermittent Claudication by Diathermy.

GRÜNBAUM (*Wien. Klin. Woch.*, October 21st, 1920), who had previously described the treatment of chilblains by diathermy (see EPITOME, March 6th, 1920, No. 245), now reports eight cases of intermittent claudication successfully treated by this method. Six were in men and two in women, aged from 41 to 56. Of the men four were heavy smokers, one a slight smoker, and one a non-smoker. Of the two women one was a heavy cigarette smoker, and the other a very moderate smoker. Syphilis was denied in all cases. In seven cases the condition was bilateral, and in one unilateral. Treatment by diathermy, which was continued for four to eight weeks, was very satisfactory. Improvement of the subjective symptoms occurred in all, and in some cases the patient was enabled to walk long distances without interruption and free from pain. Each sitting lasted ten to twenty minutes, the strength of the current varying between 400 and 800 milliamperes.

208. Radium Therapy of Acromegaly.

BERTOLOTI (*Giorn. d. R. Acad. di Med. di Torino*, March-June, 1920) records the following case: A man, aged 35, was admitted to hospital with all the signs of a rapid and malignant attack of acromegaly—namely, almost complete blindness, profound adynamia, sexual impotence, and advanced cachexia. X rays showed a tumour of the hypophysis, the size of a small nut, compressing the optic chiasma. The patient was then subjected to radium treatment, amounting in all to 7,360 mg., distributed over eight sittings during a course of four months. The irradiation was carried out exclusively over the skin of both temporal regions. Bertolotti refrained from using the intranasal route through fear of producing too violent a reaction. The result of treatment was as follows: During the first stage, which lasted from February 8th to March 13th, 1918, there was an aggravation of all the symptoms, especially as regards vision; in the second period (March 13th to July) there was slow but progressive improvement; and in the third period a complete clinical cure was effected.

209. Treatment of Pulmonary Tuberculosis by Artificial Pneumothorax.

GRAPIOLO and FOSSATI (*Rev. Sud-Amér. de Endocrin.*, September 15th, 1920) record seventeen cases of pulmonary tuberculosis treated by artificial pneumothorax. Almost all the patients had evidence of cavities, and the majority had unilateral lesions only when the treatment was commenced. The result was excellent in eight patients, good in two, two died, and seven gave up the treatment after four to twelve months' trial.

SURGERY.**210. End-Results of the Operative Treatment of Duodenal Ulcer.**

FINSTERER (*Wien. Klin. Woch.*, January 13th, 1921) has operated on 203 cases of duodenal ulcer, 27 of which occurred up to 1914, and 176 since. Up to 1914 he performed gastro-enterostomy only followed by ligature of the pylorus, but since 1915 he has almost exclusively performed resection of the duodenum and of at least half the stomach, or resection of half the stomach with exclusion of the duodenum. In 118 resections of the duodenum and stomach his mortality was 5 per cent. In the last two years, owing to increasing experience, the mortality in 21 resections had fallen to 1.4 per cent. Resection, therefore, was not so dangerous as gastro-enterostomy, in which the mortality ranged from 2 to 11 per cent. Finsterer's end-results after resection of the duodenum and after resection of the stomach had been hitherto very good. The patients felt perfectly well, had increased in weight up to 30 kilos, and had a complete absence of pyrosis—notwithstanding, in some cases, occasional alcoholic excess—although no special diet was observed. Of 63 cases of resection of the duodenum and half the stomach, which had been operated on longer than one to five years, 59, or 93 per cent., were absolutely free from symptoms, and 3 cases had occasional symptoms which were not connected with the stomach, as they could digest any food. The end-results were also good in cases of resection of the prepyloric part of the stomach, leaving behind the pylorus and the ulcer. Of 8 cases operated on longer than three to five years, 7 were absolutely free from symptoms, and of 15 which had been operated on longer than from one to three years, 13 were free from symptoms.

211. Aneurysm of the Hepatic Artery

JOSSON (*Hospitalsidende*, December 29th, 1920) reviews the literature of this subject and contributes a new case, that of a sailor, aged 27, who had recently contracted influenza twice, once with pneumonia. The symptoms were typical: sudden violent pain in the epigastrium with haematemesis. He was operated on, and the gall bladder, which was distended with clotted blood, was firmly plugged. But the aneurysm was not detected and the hepatic artery was not ligatured. The haemorrhages recurred at irregular intervals, and he died eighteen days after the operation. At the necropsy an aneurysm of a branch of the hepatic artery was found in the liver, at a depth of about 4 cm. from the surface. Apparently only seven other cases of intrahepatic aneurysm have been recorded. Extrahepatic aneurysm of the hepatic artery is, however, much more common. Villardie in 1912 collected thirty-nine cases, thirty-five of which were extrahepatic. The condition is almost invariably fatal, and only one case has been recorded (Kohns) in which the correct diagnosis was made before operation. Bode in 1909 published a case treated by ligature of the gastro-duodenal artery and several of its branches. Necrosis of the liver is the complication which surgeons dread as a sequel to ligature of the hepatic artery, but in view of the hopelessness of the prognosis in the absence of heroic measures, the author thinks that the risk of hepatic necrosis should be taken. Provided adhesions have formed about the liver, there is a possibility that they might provide an adequate collateral circulation in the liver after ligature of the hepatic artery.

212. Syphilitic Disease of the Cervical Vertebrae.

WIMMER (*Tygskrift for Læger*, November 25th, 1920) discusses the diagnosis of this condition, and points out that it usually occurs decades after infection. As it is very rare compared with tuberculous caries, the diagnosis should not be made without strong evidence. In doubtful cases the effect of anti-syphilitic treatment is of great value in the differential diagnosis. The X rays, on the other hand, seldom distinguish between the two conditions, although they may be of great value in the recognition of subacute or chronic arthritis of the vertebral column. Without specific treatment syphilitic spondylitis often terminates fatally by more or less sudden compression of the medulla, haemorrhage into the cord, or dislocation or fracture of the affected vertebrae. The case on which the author's paper is based was that of a man, aged 69, who had contracted syphilis twenty-two years earlier. He had been given forty injections of mercury soon after infection, and there had since been no eruption. No further anti-syphilitic treatment was given. In spite of Wassermann's reaction being negative in the serum and cerebrospinal fluid, and the cerebrospinal fluid being normal in

other respects, a "probability diagnosis" of syphilis was made, and was confirmed by the success achieved by injections of mercury and neo salvarsan.

213. Tuberculosis of the Larynx Cured by Galvano-cauterization.

BROCH (*Revue de laryngologie et de rhinologie*, November 30th, 1920) records a case in a girl, aged 17, suffering from isolated and clinically primary tuberculosis of the larynx, resembling a tumour. Complete recovery took place in six to eight months as the result of galvano-cauterization. In this rare form of tuberculosis, which was first described by Welles, the part of the larynx most frequently affected is the ventricle, while, at the onset at least, the rest of the larynx escapes. The lesion consists of a rounded, sessile mass the evolution of which is slow and painless. The patient is generally young, and there are no obvious signs of pulmonary tuberculosis. Removal is usually followed by a permanent cure, although sometimes active pulmonary tuberculosis or generalized miliary tuberculosis may develop.

214 The End-Result of Pneumatosis Cystoides.

NEUDORFER (*Archiv für Chirurgie*, December 4th, 1920) records the case of a man, aged 30 suffering from severe abdominal pain and vomiting. Laparotomy showed the presence of numerous gas cysts on the great omentum, and on the serous coat of the small intestine. The pylorus was transformed into a tumour almost the size of a walnut, which was adherent to the porta hepatis, and was causing a tight stenosis of the pylorus. A large number but by no means all, of the cysts were removed and posterior gastro-enterostomy was performed. Considerable improvement followed the operation, and when laparotomy was performed again eleven and a half years later, owing to return of gastric trouble, all the gas cysts had completely disappeared, and no adhesions had developed.

215 Universal Light Baths in Diseases of the Eyes

FUNDGAARD (*De ophthalmologiske*, December 29th, 1920) has for several years watched the effect of universal exposures of the body, as distinct from strictly local light treatment, on various diseases of the eyes, at the Linsen Institute in Copenhagen. He used as a rule the carbon arc lamp, and his exposures lasted fifteen to thirty minutes at first, being increased to two to two and a half hours at a later stage. After reviewing recent publications which claim almost marvellous results, the author deals separately with the following groups of cases. Phlyctenular kerato-conjunctivitis no definite improvement. Tuberculous keratitis (31 cases) found unsuitable for this treatment. Scleritis (8 cases) results variable. Diseases of the eyelid margins (58 cases), results negative in most cases, but in 2 cases, after free opening and excising, the tuberculous lesions cleared up with remarkable speed under universal light treatment. Chronic iritis and iridocyclitis (10 tuberculous cases) results good in 5 cases, in 2 cases the results were doubtful, and in 3 negative. Only in this class of case is the author inclined to indulge in qualified praise of the treatment. At an early stage of treatment there was increased local injection, suggesting a sort of focal tubercular reaction. As the treatment by universal light baths requires to be prolonged, the author feels more inclined to adopt local light treatment, supplemented by tuberculin.

OBSTETRICS AND GYNAECOLOGY.

216 Intestinal Obstruction after Ventrofixation of the Uterus

HASTED (*Ugeskrift for Læger*, December 30th, 1920) considers the risk of intestinal obstruction from fixation of the uterus to the anterior abdominal wall so great that this complication alone is enough to condemn this operation as unjustifiable. The Alexander Adams operation for prolapse of the uterus having been found also to give satisfactory results in uncomplicated cases, there is the less need for an operation which entails grave risks of fatal intestinal obstruction. None of the various modifications of the original operation for ventrofixation seems to have eliminated the risks of this complication, which are probably enhanced when the union between the uterus and the abdominal wall is dragged out into a thin fibrous band by the weight of the uterus. But even before the formation of this band the intestine may become incarcerated between the uterus and the abdominal wall, and the author records a case in which acute intestinal obstruction

occurred fifteen days after he had performed Olshausen's operation for ventrofixation. Fortunately the patient had not left hospital, and the cause of her vomiting and abdominal pain being correctly diagnosed, she was operated on early, and the obstruction was removed before the intestine had become permanently injured. The intestine was found to have slipped down through the slit between the fundus of the uterus and the anterior abdominal wall, although, at the time of the ventrofixation, care had been taken to include the upper portion of the uterus in the peritoneal suture. After removal of the two catgut sutures and closure of the abdominal wound, the patient made an uneventful recovery. This case and the study of the literature have convinced the author that ventrofixation of the uterus is an operation to be altogether discarded.

217 Premature Separation of the Normally Implanted Placenta.

ACCORDING TO VAN DER LAK (*Ned. Tijdschr. Geneesk.*, January 1st, 1921), who records a fatal case in a para, aged 38, premature separation of the normally implanted placenta at the end of pregnancy is a rare condition, only ten examples of the kind having been found by Guodcel among 106 cases of separation of the placenta. The prognosis is very unfavourable both for mother and child, being much worse than in marginal separation, of which the diagnosis is much easier. The treatment, which consists in immediate emptying of the uterus, can often save the mother, but the child very often dies. Among 106 cases collected by Guodcel only 6 children and 54 mothers survived.

218 The Physiological Anaemia of Pregnancy

GRAM (*Ugeskrift for Læger*, December 23rd, 1920) has compared the blood of forty healthy adult women (chiefly nurses) with that of fifty nine women in the last seven months of pregnancy, and has found a considerable difference in the percentage of haemoglobin in the two classes. The blood was taken by aspiration of a vein, and stabilized by the addition of an isotonic solution of 3 per cent. sodium citrate. He calculates that the percentage of haemoglobin in the blood always varies proportionately with the volume of the blood cells, the ratio of the two being haemoglobin per cent. = volume per cent. $\times 2.1$. Among non-pregnant women the average volume per cent. was 40 (= haemoglobin 84 per cent.), while among pregnant women there were only ten with a volume per cent. of 40 to 43. In 31 cases there was a volume per cent. of 36 to 39. In 18 cases the volume per cent. was less than 36. Classifying his cases according to the stage of the pregnancy, the author found that the anaemia culminated in the fifth month of pregnancy.

219 Three Spontaneous Deliveries after Caesarean Section.

GROSE (*Gynec. et Obstet.*, 1920, II, 2) records the case of a woman who underwent spontaneous delivery at term in three successive pregnancies, which followed Caesarean section practised in 1908 for dystocia due to ovarian cyst. The operation was performed forty two hours after rupture of the membranes, thirty hours after the onset of "pains," and after the failure of several attempts (made in the patient's home) to effect instrumental delivery. Linen sutures were used; several months after operation stitches were discharged from an abscess in the region of the scar.

220 Posterior Colpotomy for Puerperal Peritonitis.

At the New York Academy of Medicine (*Ned. Recort*, November 6th, 1920) SCHWARTZ, while advocating conservative treatment of puerperal sepsis, said that operative intervention would help to save life in certain cases characterized by asthenia, with ascending tenderness and pain, and by leucocytosis with increase of polymorphs. He had treated eight such cases, by transverse incision of the vaginal mucous membrane, making gentle palpation with the fingers in the peritoneal cavity, but not breaking up adhesions. This was done with the patient in bed, and after the incision had been enlarged with two fingers to give exit to any accumulation of pus that might be found, three gauze drains were introduced and left for seven days.

221 Treatment of Menorrhagia.

For severe uterine bleeding, which, in the absence of subinvolution, myoma, or other innocent or malignant uterine neoplasm, may be regarded as due to asthenia of the uterine muscle, consequent on alterations in the autonomic or sympathetic nervous elements, which the author

prefers to call "metrasthenia," MANSFELD (*Zentralbl. f. Gynäk.*, October 30th, 1920) has employed treatment by adrenalin chloride. With the object of improving the uterine tone, Mansfeld treated 25 cases by one or more injections of adrenalin chloride into the portio cervicalis; good results were obtained in 21. Of 26 cases treated by application of the solution to the cervix, 22 gave successful results. In other cases Mansfeld employs unilateral castration by x rays.

PATHOLOGY.

222. The Islands of Langerhans in Diabetes.

DUBREUIL and ANDERODIAS (*C. R. Soc. Biologie*, November 27th, 1920) record a single observation which seems to shed some light on the part played by the islands of Langerhans in diabetes. They had a patient, aged 32, who at her first confinement gave birth to a very large stillborn child; the pregnancy had been accompanied by albuminuria and eclamptic attacks. The second pregnancy was normal. In the eighth month of the third pregnancy sugar appeared in the urine to the extent of 60 grams to the litre; a very large macerated foetus was expelled at term and the sugar disappeared from the urine a few days later. The fourth pregnancy was uneventful up to the eighth month, but as the urine showed 50 grams of sugar to the litre labour was induced at the beginning of the ninth month and a very large foetus, which lived only for a few minutes, was removed. The amniotic fluid did not contain sugar, and it disappeared from the urine after seven days. *Post-mortem* examination of the foetus revealed a liver more than three times the weight of the normal organ at that period. The other organs were large but apparently normal. Of the portions preserved for examination without any preconceived line of research, only the pancreas revealed histological abnormalities. Even with a low power the enormous size of the islands of Langerhans was a striking feature, though in the normal foetus it requires some search to find them. The islands appeared as very large compact epithelial cell masses, which by calculation were on the average twenty to thirty times the size of the normal islands. Whatever be the mechanism, the general function of the islands of Langerhans is to regulate the sugar content of the blood; they maintain at a fixed titre the normal glycaemia. In this case the glycosuric mother supplied to the placenta blood highly charged with sugar; in all probability the foetal blood also obtained a superabundance of sugar. This excess of carbohydrate accounted for the excessive weight of the foetus, but it was necessary for the foetus to keep on destroying the excess of blood sugar, and such a function fell on the islands of Langerhans. Hence there was a hypertrophy of these structures and an outpouring of glycolytic ferment from them. The research, though very incomplete, as the authors admit, is suggestive.

223. The Cerebro-spinal Fluid in Early Syphilis.

SCHOU (*Hospitalstidende*, November 3rd, 1920) has made about 1,200 examinations of the cerebro spinal fluid at the Rigshospital in Copenhagen in about 800 cases of syphilis of less than three years' standing. In addition to Wassermann's reaction, the cerebro-spinal fluid was examined for cells and proteins. The cases were classified according as they had or had not been given specific treatment. In 491 cases of recent untreated syphilis morbid changes in the cerebro-spinal fluid were found in the following proportions: In 12 per cent. of 56 cases of primary syphilis in which Wassermann's reaction in the blood was positive; in 12 per cent. of 75 cases of primary syphilis with a negative Wassermann reaction in the blood; in 23 per cent. of 300 cases of secondary syphilis; in 39 per cent. of 41 cases of syphilis of six to twelve months' duration; and in 27 per cent. of 15 cases of syphilis of one to two years' duration. Commenting on these findings, the author notes that his positive results were few compared with those of many other investigators, with whose observations his own disagreed on another point—he found most of the morbid changes in the cerebro-spinal fluid in the second half-year of infection. Most of the morbid changes in the cerebro-spinal fluid were represented by pleocytosis; next in frequency was globulinose (25 per cent.), then albuminose (14 per cent.), and finally a positive Wassermann (21 per cent.). The number of cells was usually within the limits of 10 to 50 per c.m., and the three highest readings were 257, 717, and 2,500 cells. The figures for the protein content showed wide variations, probably traceable to faulty

technique, and the author concludes that Bisgaard's test is unsatisfactory in estimating the amount of small quantities of albumin.

224.

The Etiology of Goitre.

BOITEL (*Rev. méd. Suisse rom.*, November, 1920) discusses the etiology of goitre in a paper based on the study of 1,308 cases of goitre which had attended Roux's clinic at Lausanne from 1887 to 1917. His conclusions are as follows: (1) Goitre is very unevenly distributed in the Canton of Vaud. (2) This distribution seems to correspond with the physical geography of the region; its minimum incidence occurs in the Jura chain of mountains, especially on the eastern slope, and its maximum incidence in the Broye and Montevale valleys. The plain of the Rhône is also more affected than the neighbouring mountains. (3) Hereditary influence was demonstrated in 47 per cent. of the cases. (4) It could not be proved that the native population was more or less affected than newcomers. (5) Goitre had an entirely different distribution from that of typhoid fever. (6) Goitre appears to attack the rural population a little more than the dwellers in towns, but the difference is not very pronounced. (7) There is no evidence that—as claimed by Hunziker—the primary cause of goitre is absence of iodine in the district.

225.

The Corpus Callosum in Chronic Alcoholism.

LAIGNEL-LAVASTINE (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, December 2nd, 1920), from examination of the corpus callosum in two alcoholic subjects who died as a result of pulmonary complications, confirms Marchiafava's findings; the changes detected consisted chiefly in atrophic degeneration of the myelin sheaths, together with a generalized perivascular rarefaction of the parenchymal tissue, accompanied in places by microscopic haemorrhage. Both patients had shown visual and auditory hallucinations.

226.

Reticulated Red Corpuscles.

CUNNINGHAM (*Arch. Int. Med.*, October 15th, 1920) gives the details of a simple technique for obtaining permanent demonstrations of the reticulation of erythrocytes. Such reticulated cells, normally present in blood to the extent of 0.8 per cent., are much increased in certain anemias, and the appearance is generally considered to be an evidence of blood regeneration, the percentage of such cells in the blood stream giving a reliable indication of the haematopoietic activity of the blood-forming organs. The technique for their demonstration is as follows: A small drop of 0.3 or 0.5 per cent. aqueous or alcoholic solution of brilliant cresyl blue is placed on the end of a clean slide or on a cover-glass and smeared over an area of about half an inch or so by means of a match or glass rod and allowed to dry. After it is dry there may be a narrow margin of thick stain, which should be wiped off with a damp cloth, leaving a central uniform area. Such slides can be prepared beforehand and kept in stock. A fresh drop of the blood to be examined is taken on a clean cover-slip, and this is dropped face downwards on to the prepared slide. The blood quickly spreads, and the stain goes into solution almost immediately. The cover-glass is now pulled apart from the slide, and after drying is stained with Wright's blood stain. It may be mounted in Canada balsam and kept for months. The reticulum is stained blue, and gives a striking picture in contrast with the pink protoplasm of the cell.

227. Are there Several Strains of Gonococcus?

THOMSEN and VOLLMOND (*Hospitalstidende*, November 3rd, 1920) have carried out investigations at the Serum Institute in Copenhagen on cultures of gonococci obtained from the male urethra in 26 cases early in the disease. They suspected that the lack of uniformity of the reaction of various cultures of gonococci to serological tests might be due to differences of strain, such as have been recently demonstrated in the case of pneumococci and meningococci. They also wondered whether it might not be possible to correlate serological peculiarities of certain strains with peculiarities in the clinical picture. After describing in detail their serological test-complement fixation, agglutination, etc., they conclude that of their 26 pure cultures, 14 could be classed under one heading (Type A), 5 under another heading (Type B), and 5 under a third heading (Type C). The remaining 6 cultures could not be fitted into any of the above three classes. Of the 14 belonging to Type A, 5 were complicated by epididymitis and prostaticitis. Of the 5 cases belonging to Type B, 3 were slight, 2 were protracted. All the 5 belonging to Type C were slight and uncomplicated.

AN ADVANCE IN TREATMENT

"Byno" Lecithin

Indicated in all
Nervous Disorders
Mental Strain and
General Debility

Lecithin preparations are recognised as possessing valuable therapeutic properties in the treatment of Nervous Debility, whether of primary origin or secondary to acute or chronic disorder. "Byno" Lecithin exerts stimulating action on both the nervous and digestive systems. The preparation is readily assimilable, the combination with malt ensuring easy digestion.

A British Medical Association Lecture

OF

VACCINE THERAPY IN REGARD TO
GENERAL PRACTICE.*

BY

ALEXANDER FLEMING, F.R.C.S.,

DIRECTOR OF THE DEPARTMENT OF SYSTEMATIC BACTERIOLOGY AND
ASSISTANT DIRECTOR OF THE INOCULATION DEPARTMENT, ST. MARY'S HOSPITAL.

I HAVE been practising vaccine therapy since it was in its infancy, and as time goes on I find myself more and more convinced of its efficacy, not only for the more severe cases which are to be seen at a hospital, but also and more especially for the lesser ailments which seldom appear at a hospital, but with which the practitioner has much to do.

An enormous amount of work has been done in the elucidation of the changes which take place in the animal body following the injection of a vaccine and much still remains obscure, but I confine myself to putting before you the clinical aspects of vaccine therapy in general, and to dealing with the treatment by vaccines of certain conditions, more especially those in which there have been advances made in the last few years.

DEFINITION OF A VACCINE.

A vaccine is a substance which, when injected into the animal body, induces the formation of specific antibodies.

This definition makes the term "vaccine" synonymous with the word "antigen." Originally vaccines were differentiated as being preparations of bacteria, but now various protein extracts—for example, pollen extract—are used in the same way in the treatment of disease, and there seems no reason why the term vaccine, if retained at all, should not be used in the wider sense to include all antigens. In the narrower sense, a vaccine may be defined as a standardized suspension of micro-organisms in an inert fluid.

AUTOGENOUS AND STOCK VACCINES.

An autogenous vaccine is a vaccine prepared from cultures obtained directly from the patient. A "stock vaccine" is made, not from cultures obtained from the particular patient who is being treated, but from cultures of the same type of microbe as that which is affecting him. In the preparation of a stock vaccine a considerable number of strains should be employed in order to eliminate as far as possible any small differences there may be in the individual strains.

Should a Stock Vaccine be Used or an Autogenous One be Prepared?

This is not always an easy question to answer. In practice it is frequently dealt with from the point of view of expediency. In many cases where the infecting organism is easy to cultivate and the vaccine is easy to prepare, it is less trouble to prepare an autogenous vaccine than it is to identify the organism exactly. On the other hand, the isolation of the microbe and the preparation of the vaccine is frequently a very tedious and laborious proceeding, and in such cases, if the nature of the infecting agent is obvious, then a stock vaccine is often employed and an autogenous vaccine made only if the stock vaccine fails. In connexion with this question four different classes of cases have to be considered.

Class 1.—Where the vaccine is to be used for prophylaxis.

It is clear that here we have no choice. Only stock vaccines can be used. The fact that stock vaccines have been used with such signal success in the prophylaxis of typhoid, paratyphoid, cholera, plague, and the catarrhal infections of the respiratory tract, is of the utmost importance in that it shows that it is not necessary to insist on a vaccine being made of a microbe of exactly the same parentage as the infecting microbe so long as it belongs to the same species.

Class 2.—Where the nature of the bacterial infection is known but a culture of the microbe cannot readily be obtained from the patient.

Such conditions occur in connexion with tuberculous infections or where the infection is deep-seated—for instance, in the joints or glands. In such cases, again, there is almost no choice and we have to use stock vaccines, and the results which have been obtained with these in such cases show that good immunizing responses can be induced.

Class 3.—Where, owing to the profusion of contaminating microbes, it is difficult to identify and differentiate with sufficient sharpness one microbe from another of the same morphological species.

This applies especially to chronic catarrhal conditions of the respiratory and alimentary tracts, to putrid infections of wounds, and to the erosions often associated with malignant tumours. Here only a very experienced bacteriologist will be able to make satisfactory autogenous vaccines. In some cases it is quite impossible from the examination of a single specimen to say which of the many microbes present is the infecting agent, and in almost all it is extremely difficult to say which of the many varieties of streptococci is really causing the infection and which are merely leading a saprophytic existence. It will be advisable in many such cases, therefore, for treatment, and still more for prophylaxis, to employ the polyvalent stock vaccines made from a large number of strains of the microbes in question, especially as the stock vaccine can be prepared from cases in which there is no doubt as to the nature of the infection.

Class 4.—Where the infecting microbe can easily be obtained from the patient in pure culture.

These cases are very common, and when we have to choose between an autogenous and a stock vaccine in such conditions we have to balance the possible advantage of an autogenous vaccine against the labour and expense involved in procuring it.

A stock vaccine is indicated when the infecting organism belongs to a group the members of which differ very little among themselves. Thus, in staphylococcus infections, a stock vaccine will in almost all cases give as good results as an autogenous, and in some few cases the stock vaccine will prove the more beneficial. Occasionally a strain is encountered which proves to be a bad antigen, and if such a strain is isolated from a patient and an autogenous vaccine made little benefit will be derived from its use, whereas in the same case the stock vaccine, containing, as it does, a number of strains which have proved to be good antigens, would give a good result.

With *Streptococcus pyogenes* also, which is the cause of erysipelas, cellulitis, lymphangitis and many other septic conditions, it has been shown that if an animal is immunized to one strain its serum will agglutinate to the same extent all the strains. This experimental observation is in accordance with the fact observed clinically that *Streptococcus pyogenes* vaccine is one of the most effective of the stock vaccines.

Some species of bacteria, such as pneumococci, which were formerly thought to be very homogeneous groups, have recently been split up by immunological methods into three or four subgroups, and it is essential that a stock vaccine of these organisms should contain representatives of all the groups. When this is done stock vaccines of these organisms are very effective.

In connexion with some bacteria, such as *B. proteus*, it has been found that some of the strains when injected into animals give a good immunizing response against all the different strains of the microbe, while others give immunity only to one or two strains. When dealing with such microbes it is essential that the stock vaccine should be made from strains of general antigenic power and not from strains which are merely partial antigens. If the stock vaccine is not made in this way it is better to use an autogenous vaccine.

Other organisms, such as Pfeiffer's bacillus of influenza, differ even more one from another in their antigenic powers, so that if an animal is immunized with only one strain its serum will agglutinate that strain and not more than a very small proportion of the other strains. In such a case the stock vaccine must be made from a very large

* Delivered before the Maidstone Division of the British Medical Association.

number of strains to ensure a wide polyvalency. A stock vaccine of Pfeiffer's bacillus made in this way has proved extremely efficacious, but in view of the immunological differences between the different strains an autogenous vaccine should be preferable.

A stock vaccine is indicated also in acute cases where it is desired to proceed with vaccine therapy at once without waiting for the preparation of an autogenous vaccine. In such cases it may be given in small doses while the autogenous vaccine is being prepared. If this is done it will often be found that by the time the autogenous vaccine is prepared the condition will have improved to such an extent that there will be little need to use it.

It is desirable to use an autogenous vaccine (a) when the infecting agent belongs to an ill-defined group of microbes. This is well exemplified in the so called "B. coli infections," for the name is loosely applied to a large group of organisms which, as regards their antigenic properties, are very different. It is therefore more satisfactory in such infections to employ an autogenous vaccine. (b) When the infection is severe and it is felt to be too great a risk to wait to see whether the stock vaccine is effective; but it is wise in such cases to give a small dose of the stock vaccine while the autogenous one is being prepared. (c) When treatment with a stock vaccine has failed.

CLINICAL EFFECTS.

The clinical effects of the injection of a bacterial vaccine may be divided into two classes: (a) toxic and (b) immunizatory.

Toxic Effects.

These follow soon after the injection and the term "reaction" is applied to them. They fall under three headings:

1. *Local Reaction.*—This is the effect produced at the site of the inoculation. It varies enormously in the same individual with different vaccines and in different individuals with the same vaccine, and the intensity of the reaction has no known bearing on the general changes occurring in the individual in response to the inoculation. It varies from nothing at all to a brawny swelling extending for some distance from the site of the inoculation. Usually it consists merely of a slight local swelling and tenderness, and causes little discomfort. Apart from this discomfort it is of no importance. The local reaction is always more severe when the injection is made in a region which is subject to pressure of the clothing, or which does not contain much subcutaneous fat, and is situated over muscles which are constantly in use (for example, the forearm). The best sites for inoculation seem to be in women about two inches below the centre of the clavicle or behind the shoulder, and in men the flank also is very suitable.

2. *Focal Reaction.*—This is the term applied to the effect of an inoculation of vaccine on the focus of infection. With a small dose there is no apparent focal reaction. With a larger dose there is some increase of the inflammatory signs in the infected focus. With a very large dose there may be a very great exacerbation of the symptoms which may result in the necrosis of the infected tissues. With the average dose there is, however, little or no focal reaction.

3. *General Reaction.*—Small doses of vaccine are not followed by any general toxic manifestations, but very large doses are apt to be followed after a few hours by signs of a general intoxication. A mild general reaction consists merely of a little malaise, but if the reaction is severe then there may be rigors, sweating, high fever, and even diarrhoea, sickness, or collapse. Doses of vaccine causing severe reactions should never be used. This general reaction is caused in part by the toxic substances which are introduced in the vaccine, but it is also probably caused largely by the absorption of toxic material from the infected focus which has at the same time been much disturbed by the focal reaction.

Immunizatory Phenomena.

1. *Focal.*—These focal changes vary so much in their character, and the time it takes for any appreciable benefit to ensue varies so much with the nature of the infection, that it is not possible to generalize further than to say that after twelve hours or longer there is a diminution in the inflammatory symptoms.

2. *General.*—Usually the first beneficial effect following the administration of a vaccine is a feeling of well-being in the patient. When small doses are used this may follow within an hour or two, and it is frequently very striking. When the patient is running a slight temperature, a small dose of vaccine administered in the morning will bring the temperature down the same evening. This fall in the temperature coincides with a rise in the antibacterial content of the blood.

It has frequently been urged that in acute cases it is of little use to give vaccines, as it takes a week or more before any result of the vaccine can be seen. As I have stated above, the beneficial result of a suitable dose of vaccine may be manifest in a few hours, and a reference to the accompanying chart will show the effect of the correct dose of vaccine on the temperature chart. It will be observed that the effect of the vaccine administered about midday

was to prevent the evening rise of temperature the same day and to keep the temperature down for some days. The same effect on the temperature is seen after the second inoculation.

The patient to whom this chart refers was suffering from a septic compound fracture of the femur, and for about three weeks had had a septic type of temperature similar to that for the three days indicated in the chart previous to the inoculation.

DOSAGE OF VACCINES.

Speaking generally, the aim of the vaccine therapist is to give the maximum dose which will not give rise to a general reaction in the patient. In the consideration of the dose which is to be administered to any particular patient there are several factors which have to be taken into account. In the first place, it is a general rule that the more severe the infection the smaller should be the dose of vaccine administered. This, on the face of it, does not seem to be unreasonable, as the patient who is suffering from an acute infection is absorbing much toxic bacterial substance from the focus of infection, and if a large dose of vaccine is administered on the top of this, then it may easily constitute an overdose, and it is in just such a case that an overdose is to be avoided. Secondly, the toxicity of the particular vaccine which is going to be administered has to be considered. Some vaccines can be given in large doses, even in acute cases, without the slightest reaction, whereas with others great care must be taken in feeling one's way, otherwise an alarming reaction may occur. Thus, with *Streptococcus pyogenes* in an acute case it is well to begin with not more than two million cocci, whereas with Bordet's bacillus of whooping-cough or with Pfeiffer's bacillus of influenza very large doses can be given even in acute cases with impunity. In connexion with the dosage of vaccine, therefore, we have to consider several different classes of cases:

1. Where the infection is a chronic one, and where even if there is a small flare up it will not seriously inconvenience the patient—for example, syphilis or farunculosis. Here the dose should be rapidly increased—and by a rapid increase I mean successive increments of 50 to 100 per cent.—until there is a very marked improvement or until there is evidence that a slight overdose has been given as evidenced by an exacerbation of the local condition or by some fever or malaise after the inoculation—that is, until there is a focal or a general reaction. When there is evidence of this overdose, then the next dose should be reduced to the last one which failed to produce any "reaction," and the subsequent increases should only be gradual. If there is marked improvement before any "reaction" is evident (as is very often the case), then the same dose which has induced the improvement should be repeated several times, as evidently something approaching the optimum dose for the particular patient has been found.

2. Where the infection is a chronic one, but where it is not safe to risk any considerable exacerbation of the condition

—for example, chronic bronchitis. Here the best procedure is to give a safe dose and to increase the dose only gradually. By this means improvement will be seen without any danger of upsetting the patient. A little time may be lost in finding the most suitable dose, but in such a case this is infinitely preferable to the risk of setting up an acute infection.

3. In acute infections where it is essential that no "reaction" should be induced—for example, bronchopneumonia, erysipelas, etc. The same procedure should be adopted as in the preceding case, but the initial dose should be smaller (roughly one-quarter). In cases of this description it is wise to give very small doses and to repeat them often (every twenty-four or forty-eight hours if necessary). In all cases where with a certain dose there is definite improvement manifested, it is wise to repeat the same dose next time and possibly for several times. If, instead of doing this, the practitioner increases the dose according to a definite prearranged scale, then it is quite likely that he will rapidly increase the dose beyond the optimum and undo all the good which he has done with his first doses.

Here I should like to put in a word of caution to the practitioner against slavishly following the scale of doses which commonly accompany a vaccine from the laboratory. In many cases an autogenous vaccine is sent out from a laboratory in a series of ampoules, each ampoule containing a larger dose of the vaccine than its predecessor, and in many cases these doses are injected into the patient at intervals of a week or thereabouts without regard to the action of any one of them on the patient's condition. The scale of doses is given in all good faith by the bacteriologist, but it must be remembered that at the best this scale only represents the average dose and any individual may differ far from the average. It must be remembered, also, that in a great many laboratories, and especially in the commercial laboratories not attached to hospitals, the bacteriologist may have very little experience of the actual treatment of patients with vaccines, however skilful he may be at the isolation of bacteria and the preparation of vaccines. His opinion, therefore, as to the dosage of the vaccines is often taken only from what he has learnt from someone else, and it may be extremely fallacious.

A Successful Result with Vaccine Therapy.

When the microbes are exposed to the full effect of the antibacterial substances elaborated as a result of the injection of vaccine, then the result should be rapid and favourable. When, on the other hand, the microbes are enclosed in inflammatory tissue and in tissue where, as a result of the inflammation there is a greatly diminished blood and lymph supply, they will be partially sheltered from the antibacterial substances and the result will be much slower and less certain. Where the microbes are contained in some necrosed material such as a slough or sequestrum, it is unlikely that the antibacterial substances which may be produced will have any influence on the bacteria which are so hidden, although they may limit the infection and prevent its spread to the surrounding tissues.

It follows from this that in incipient infections a rapid success may be obtained, but where the infection is of old standing and the circulation through the infected focus has become impeded success will only be obtained after a long series of immunizing doses, while in cases where there are sloughs or collections of pus success with vaccines will only be obtained after the sloughs have been removed or the pus has been evacuated by surgical means.

When a vaccine is given for prophylactic purposes it is not to be expected that the immunity will be absolute. Even when an individual is highly immune he may receive such a large dose of a virulent organism that infection will result. It is doubtful whether a vaccine will ever be produced which will confer such immunity that the individual is resistant to the strongest infection. The vaccine will, however, confer immunity to a moderate infection, so that a disease like typhoid fever, instead of assuming epidemic proportions, will occur in an inoculated community only in a few individuals here and there who have either received an enormous infection or whose immunity may have been temporarily reduced by privation or other cause.

CLINICAL APPLICATION.

I now wish to discuss the vaccine treatment of some of the conditions which are common in general practice.

Catarrhal Infections of the Respiratory Tract.

I will commence with these first, because at this season of the year they are very much in evidence, and secondly, because in no conditions is the practitioner likely to achieve greater success with vaccines.

The bacteriology of the whole respiratory tract is roughly the same, and the three microbes which are most commonly in evidence in infections of this region are the pneumococcus, streptococcus, and Pfeiffer's bacillus of influenza. There are others, such as the *Micrococcus catarrhalis*, *Bacillus septus*, Friedlander's pneumonia bacillus and staphylococcus, which are at times found, but infections with these are not so common.

In all these catarrhal infections of the respiratory tract we must bear in mind that we are all constantly being exposed to infections with one or other of these microbes as the number of carriers is legion. It was shown during the war that when there was an epidemic of cerebro spinal meningitis—which is caused by an organism which inhabits the respiratory passages—there were among the people of the infected camps a very large number of carriers. During the influenza epidemic it was shown that in some communities more than half the population were harbouring in their respiratory passages the pneumococcus and Pfeiffer's bacillus, while it is probable that nearly all of us constantly have pathogenic streptococci in the mouth and post-nasal spaces. It is evident, therefore, that every one is being very frequently brought into contact with these microbes which are responsible for the catarrhal conditions, and there is no doubt that we have all acquired a certain amount of immunity. It is common knowledge that individuals vary enormously in their susceptibility to these infections: some people hardly ever get colds, others are constantly picking them up.

When we examine these "colds" bacteriologically we find that while some individuals (and these are in the minority) get many "colds" which are always caused by the one microbe, others (the majority) are infected by one microbe at one time and by another at another time. The same is seen in many cases of chronic bronchitis. The flora is not constant, but one microbe may be there for a time and then it will disappear and its place will be taken by another. This varying flora makes the treatment of respiratory conditions more complicated, but it has had one good effect as regards the vaccine treatment by the practitioner, and that is that it has caused the mixed polyvalent vaccines to be introduced. For routine vaccine therapy practice where many patients have to be dealt with, and where there is not the opportunity of having extensive bacteriological investigations done on each patient, these polyvalent mixed vaccines have met with very great success.

When a sputum is sent to the laboratory from a case of chronic bronchitis, often there is found a very mixed flora, and it is extremely difficult to say which is the infecting organism and which of the organisms are merely growing saprophytically. In such cases better results are very often obtained with the mixed stock vaccines than can be got with autogenous vaccines. There is no doubt that in the period before the influenza epidemic, in very many cases of chronic bronchitis, Pfeiffer's bacillus was missed in the examination of the sputum; it is not very easy to see in a stained specimen of sputum, and the methods of cultivation were very indifferent, so that in very many cases autogenous vaccines were made which did not contain this, which was probably the most important part of the infection.

The Common Cold.—The mixed stock vaccine (0.2 c.c.m.) should be given immediately the "cold" is noticed, and in a certain number of cases the attack will be aborted. Even when the cold has developed, the vaccine will generally cut short the attack, and especially the last stage, when there is a profuse muco-purulent discharge from the nose without constitutional symptoms. The vaccine also seems to prevent the infection spreading down to the bronchi. With the common cold, however, the chief value of the vaccine is in prophylaxis. In people who are susceptible to colds the anticatarrhal vaccine should be given in the

autumn in three doses—0.25, 0.5 and 1 c.cm.—and during the winter monthly doses of 1 c.cm. may be given. It has been common experience that by this means people can be kept free from colds who, without the vaccine, were having one attack after another during the winter.

Bronchitis.—The bacteriology of bronchitis is roughly the same as that of the common cold, and very often the attack begins with a cold. If the infection is simple, an autogenous vaccine may be made, but usually the mixed stock vaccine does all that is necessary. Doses of from 0.25 to 1 c.cm. of the mixed vaccine for colds or of the anti-rhach vaccine are given at intervals of from three to seven days, and after the first one or two doses the patient notices the improvement. The condition usually improves rapidly up to a point at which it gives little trouble to the patient, and when this stage has been reached, if larger doses are given monthly the infection gradually disappears.

Influenza. By this term I mean the acute epidemic influenza and not the catarrhal conditions which are loosely called influenza by the public. During the recent epidemic vaccines have proved of very great benefit both in the prophylaxis and in the treatment of the complications of this disease. The primary cause of the infection is unknown. There are two schools; one holds that Pfeiffer's bacillus is the primary infection, and the other that the nature of the infection is yet unknown. There is not the slightest doubt, however, that Pfeiffer's bacillus, together with the pneumococcus and streptococcus, is responsible for the complications of the disease, and it is to them that the bronchopneumonia which caused the mortality was due. Exact figures as regards the influence of the vaccine on the epidemic were not easy to obtain, but a very interesting and important communication was published by Sir William Leishman, on the results in the military camps in England during the last wave of the epidemic, which showed that the incidence of the disease was reduced from 47.3 to 14.1 per 1,000 and the mortality from 2.25 to 0.12. Even allowing a very considerable margin of error, these figures are quite enough to prove that the vaccine was of enormous benefit in reducing the mortality. The vaccine which was used in these experiments was one which only contained a small dose of Pfeiffer's bacillus, and it has now been modified, so that it is more than likely that with the new vaccine the results would be even better than is shown by Sir William Leishman's figures. As regards the composition of the anti-influenza vaccine, there are many different combinations on the market containing varying proportions of the three microbes which are involved. Of these different vaccines, I think that the best combination is the one which we prepare at St. Mary's Hospital, which contains 500 million Pfeiffer's bacillus per cubic centimetre, with 1,000 million pneumococci and 100 million streptococci. The Ministry of Health vaccine contains a smaller dose, and especially a smaller dose of the pneumococcus, and is really a compromise between the old army formula and the St. Mary's Hospital formula. It has been shown, especially by Lister in South Africa, and by the American army authorities during the war, that very large doses of pneumococcus can be given with impunity and that better immunity followed these larger doses than was obtained with the smaller ones.

Treatment.—It has been the experience of many practitioners that small doses of one of the anti-influenza or anti-catarrh vaccines was of very great benefit in the treatment of the bronchitis and bronchopneumonia which followed influenza. Doses of about 0.1 c.cm. of the prophylactic vaccine were given immediately and repeated in twenty-four hours if the temperature still remained high.

Pneumonia.

During recent years great advances have been made in the treatment, and more especially the prophylaxis, of pneumonia by means of vaccines.

In 1913 Sir Almroth Wright published results showing that among the natives employed on the mines in South Africa the administration of vaccines had a very definite effect in reducing the incidence of and mortality from lobar pneumonia. He also showed that vaccine given in the incubation period not infrequently aborted the attack—this latter observation proving that the administration of pneumococcus vaccine was not followed by any prolonged

negative phase such as sometimes follows typhoid vaccination. At the time that Sir Almroth Wright's observations were made it was not appreciated that pneumococci differed among themselves as regards their antigenic properties, but soon after it was shown by Dochez and Gillespie that pneumococci could, by immunological methods, be split up into several groups more or less definite. These observers found that there were three definite groups of pneumococci, and besides these there were a number of cocci which did not fall into these groups, and these they made a conglomerate group which they designated Group 4. It was shown that a vaccine of a pneumococcus of Group 1 would protect against an infection of Group 1 but not against the other groups; Group 2 vaccine would protect against Group 2 but not against Group 1, and so on. Lister, who continued Sir Almroth Wright's work in South Africa, ascertained which were the common types of pneumococci causing pneumonia on the Rand, and he prepared a mixed stock vaccine containing all the types, which he administered to the natives in large doses with wonderful effects as regards the prevention of the disease. The table given below, which is taken from Lister's work, refers to the incidence and mortality of pneumonia on one of the large mining compounds where there was a native population of something like 15,000 men, and it will be seen that whereas the incidence

Table showing the Pneumonia Returns of one of the South African Mines for the Years 1908 to 1915, also for the Experimental Period from November, 1916, to October, 1917, inclusive.

Year.	Incidence per 1,000.	Mortality per 1,000.
1908	70.71	14.17
1909	104.85	17.97
1910	153.54	26.97
1911	128.93	26.94
1912	67.68	19.96
1913	31.75	4.83
1914	—	—
1915	—	—
Experimental period, November, 1916, to October, 1917	4.67	0.85

* During these years the inoculations were carried out in accordance with the principles advocated by Sir Almroth Wright and his associates.

† No record on account of war conditions.

of pneumonia before vaccine therapy was instituted was 70 or more per 1,000, it dropped during the year when Lister was giving his vaccine consisting of mixed types of pneumococci to about 4 per 1,000. The effect on the mortality from the disease was even more striking, as this dropped from about 20 per 1,000 to 0.85. There can be no question from these figures that pneumococcus vaccine is of extreme value as a prophylactic, and if further evidence was required it is furnished in the various reports from the camps of the United States army during the war. Pneumonia was one of the great scourges of the American camps, but by the use of vaccines the incidence and mortality from this disease was much reduced.

As regards the treatment of lobar pneumonia with vaccines it is much less easy to obtain reliable figures owing to the great variations which are observed normally in the course of the disease. Wright's observation that the disease can be prevented by inoculation during the incubation period shows that large doses of the vaccine can be given with safety and without producing a negative phase, and a number of reports have been published showing that the administration of vaccine shortened the disease and hastened the crisis. It must be remembered, however, that when the lung is consolidated there is a very large amount of tissue swarming with pneumococci through which the circulation is greatly impeded, so that even if a certain amount of immunity is produced the immune bodies will have difficulty in obtaining access to the seat of infection. There seems to be no doubt that the administration of vaccine aids the resolution of the pneumonia and hastens recovery.

Whooping cough.

This disease is caused by Bordet's bacillus, but very soon after the onset there appear, just as we see in influenza, Pfeiffer's bacillus and pneumococcus. For the treatment of the disease, therefore, a mixed vaccine should be given. The technical difficulties of isolating Bordet's bacillus make it almost imperative in practice to use a stock vaccine, and such a vaccine should contain all three of the bacteria mentioned above. This vaccine is very little toxic, so that even for small children, comparatively large doses (1,000 or 2,000 million) can be given, and it is well to repeat the doses every two or three days instead of at the longer periods which are common with the other vaccines.

The administration of the vaccine cuts short the attack and prevents complications.

It is for prophylactic purposes that the whooping-cough vaccine will be found of greatest value to the community. Either a simple vaccine of Bordet's bacillus may be given or a mixed vaccine of this bacillus combined with Pfeiffer's bacillus and pneumococcus. Three doses of the vaccine should be given at intervals of a week, and it has been found that in some communities of children whooping-cough has been almost wiped out by this means. I should strongly advocate prophylactic vaccination in institutions where there are aggregated together numbers of children, and also in families where one of the children has become infected.

Chronic Rheumatic Conditions.

I include under this heading rheumatoid arthritis, fibrositis, neuritis, sciatica, myositis and similar complaints. These all seem to take their origin from some chronic infection, which is usually streptococcal. The site of the infection is usually in the mouth or the intestine, and the streptococcus which is responsible is very different from the *Streptococcus pyogenes*, which is the causative agent in acute septic infections such as erysipelas or acute septicaemia; it is of very much less virulence, so that it may infect a portion of the body for years without causing more than slight inconvenience. It is because of this that infections of this type are allowed to persist, maybe, for many years, and it is often only when some serious result, such as rheumatoid arthritis, is seen that any attention is paid to the original infection. A common history of a patient with rheumatoid arthritis when she comes to the out-patient department is that she had had teeth for years, and when she consulted her doctor she was told to have all her teeth out. This was followed by only temporary improvement, after which the arthritis progressed as before. On examination of such a patient's stools, it will in all probability be found that there is an enormous preponderance of streptococci, and more especially of streptococci of the mouth type. Doubtless the infection commenced in the mouth, but some of the streptococci which were being continually swallowed escaped destruction by the gastric juice and bile and established themselves in the intestine, where they had continued to flourish.

The effect in such cases of the administration of vaccines, either autogenous or stock, has been that in almost all there is some alleviation of the condition, and in some there is apparently complete disappearance of the disease. In some few there is apparently no benefit, which is not surprising considering the difficulty in isolating the organisms from the intestine and the multiplicity of types of streptococci found there. Considering, also, that the source of the streptococci is the intestine, which is to all intents and purposes outside the body, it must be appreciated that the course of vaccine treatment must be long, and it is seldom that recovery will take place in less than a year. Owing to the multiplicity of types of streptococci in the mouth and intestine it is frequently better to commence treatment with a mixed stock vaccine such as the anti-rheumatic vaccine which we make at St. Mary's Hospital and which contains a very large number of strains of streptococci from rheumatic patients, and only to proceed with an autogenous vaccine if the stock vaccine fails. If this is done, only comparatively seldom will an autogenous vaccine be required.

Diphtheria Carriers.

Brownlie (*Lancet*, March 27th, 1920) showed that by the administration of a vaccine the diphtheria bacilli could be

got rid of in a very much shorter time than by any other means. Out of a series of 50 consecutive and unselected cases who received the vaccine in doses of 10 to 60 millions every four days 44 were free from bacilli after three doses, and all were free after eight doses of the vaccine. If these observations are confirmed it would seem that for public health purposes this vaccine of the diphtheria bacillus would be of the greatest value.

Other Conditions Suitable for Vaccine Treatment.

Vaccine therapy is applicable to very many conditions other than those on which I have touched, but time prevents my going into these. Local tubercle, acne, staphylococcal infections such as boils and carbuncles, streptococcal infections such as erysipelas or pyorrhoecia, and many others have been successfully treated, and indeed vaccine therapy in these conditions seems to furnish the only direct means of combating the infection. Many publications have been made on these matters, and I need not weary you with recital of the merits of vaccines in these conditions which have been treated in this way for many years.

In conclusion, I wish to draw attention to the fact that patients may be inoculated with bacterial products not only from without, but also introduced into their circulation by some disturbance of the infected focus. It has been shown by means of blood examinations that any such disturbance is followed by a sequence of events which are the exact counterpart of those following the administration of vaccines by hypodermic injection.

It does not matter what form the disturbance takes—whether exercise, massage, forcible movement or the active hyperaemia induced by the application of a fomentation—the result is the same, the only difference being that, whereas the light forms of disturbance reproduce the effect of a small dose of vaccine, the more severe disturbances may be followed by the same events which follow a large dose of vaccine, and to which I have alluded above under the heading of "General Reaction"—namely, malaise, fever, or even collapse.

It follows from this that in the treatment of any patient by vaccines a satisfactory conclusion is only to be arrived at if this phenomenon of auto-inoculation is considered, and in most cases it is necessary that these auto-inoculations should be diminished or abolished by keeping the infected part as much as possible at rest by splinting or some other means.

In some conditions, such as phthisis, it is very difficult to control these auto-inoculations, and it is probable that the very indifferent results which have followed the administration of tuberculin in this condition in many cases have been due to this fact.

THE SEROLOGICAL CHARACTERS OF DISEASE-PRODUCING PNEUMOCOCCI.

BY

RICHARD R. ARMSTRONG, M.D., M.R.C.P.,

ERNEST HART MEMORIAL SCHOLAR, BRITISH MEDICAL ASSOCIATION (1919-1920).

(From the Bacteriological Department, St. Bartholomew's Hospital.)

RECENT investigations on several groups of micro-organisms, of which the meningococci group may serve as an example, have proved the value of discrimination between disease-producing strains on the one hand and non-pathogenic saprophytes on the other. Such discrimination has been rendered possible by the general method of testing the agglutination reaction of a particular strain against specific serums, previously prepared by inoculation of rabbits with typical organisms from morbid lesions. By this means disease-producing micro-organisms have been gradually relegated to types.

The diversity of the clinical picture presented by pneumococcal pneumonia, the wide prevalence and severity of this disease, and the fact that the pneumococcus is a normal and usually harmless inhabitant of the upper respiratory passages, has suggested that distinct disease-producing types of the organism may exist.

Such has been shown to be the case by American workers at the Rockefeller Institute for Medical Research,

who have defined at least three serologically distinct types to which the great majority of pneumococci isolated from actual cases of pneumonia were found to belong; a number of strains from indifferent sources, such as saliva or nasal secretion, could not be grouped by the type serums.

Application of the American results to pneumonias occurring in this country was at once suggested, but having regard to our widely different climatic and social conditions, it did not seem sufficient to limit investigation to the typing of pneumococci by means of serums obtained from American sources only.

It was held that insufficient evidence of the relative prevalence of the three recognized American types in this country was available, nor was there proof that other types of pneumococcus, as fertile originators of disease as any recognized in America, might not exist here. Further, it was considered inconvenient that the serological test should depend on the availability of serums derived exclusively from American sources. The preparation at first hand of type-agglutinating serums appeared expedient therefore, both from the standpoint of excluding the necessity for importing supplies, and also in order to obtain agglutinating serums prepared against strains of pneumococci derived from home sources. Experiments have been carried out with these objectives in view, and the results obtained will be considered under two headings:

I. The serological characters of pneumococci isolated from a variety of cases of pneumococcal infection not only of the lungs, but of the respiratory tract in general.

II. The preparation of agglutinating serums by the inoculation of rabbits with pneumococci derived from British sources.

I. SEROLOGICAL CHARACTERS OF PATHOGENIC PNEUMOCOCCI.

1. Identification of the *Pneumococcus*.

The identification of each strain of pneumococcus prior to investigation by the serological test has been based on the characters described below—namely:

1. *Habits*. The source—for example, sputum or lung juice; or heart's blood culture in a fatal case of pneumonia.

2. The very characteristic appearance of colonies on solid media. These are ringed or discoid in shape, and have an appearance resembling ground glass.

3. Pneumococci, particularly of pathogenic strains, show extraordinary predilection for media enriched with fresh blood. Although the addition of other body fluids (ascitic, etc.) will promote growth, the haemophilic character of the pneumococcus appears characteristic, and herein the organism differs from streptococci; the size of streptococcus colonies does not appear to be quite so much affected by the presence of blood.

4. Uniform turbidity in blood broth and ascitic broth; relative absence of chains.

5. The shape of the pneumococcus is usually a valuable guide; the presence of a capsule when growing in material obtained from body fluids is of important diagnostic value.

6. Mair's modification of the bile-solubility test has been employed.

One-tenth of a cubic centimetre of a 10 per cent. solution of sodium desoxycholate is added to a twenty-four-hours old culture in 4 c.c.m. of sugar-free broth enriched by the addition of half a cubic centimetre of ascitic fluid.

If a pneumococcus be present, the turbid culture almost immediately clarifies; on the other hand, control tests with similar cultures of *Streptococcus pyogenes*, *salivarius*, and *faecalis* are absolutely negative.

2. The Serological Test.

An epitome of the procedure employed in carrying out the serological test follows:

TECHNIQUE.

A. Preparation of the Standard Emulsion.

1. Single colony subcultures are made from first cultures of the material under investigation on—

2. Surface plates of legumin agar containing incorporated fresh human or rabbit's blood.

3. Plates are incubated at 37° C. overnight.

4. The growth is washed off in normal saline solution.

5. The suspension thus obtained is heated to 65° for half an hour.

6. Standardized to required strength—for example, 4,000 million cocci per cubic centimetre—and phenolated by the addition of 5 per cent. phenol solution requisite to produce a final concentration of 0.5 per cent. phenol.

B. Agglutination.

1. Small glass tubes 3 in. by $\frac{1}{2}$ in. are arranged in racks for incubation at 55° C.

2. Required—control normal rabbit's serum, the three type serums, and suspensions of the three type cocci.

3. Dilutions of 1 in 10, 1 in 20, 1 in 40, 1 in 80 of serum, of each 0.5 c.c.m. Add an equal amount of suspension to all tubes and incubate.

4. In marked cases results are easily readable within four hours, but as a routine twenty-four hours are given.

5. Agglutination when positive is generally complete in the case of typical specimens. Any supersensitiveness of coccal suspension to serum is betrayed by the control with normal serum.

For brevity and clearness results have been expressed as far as possible in the table on page 261, which summarizes the clinical features of each case, records the source from which coccus was derived, whether sputum, etc., during life or material obtained *post mortem*. The appearance of films of such material and of the primary cultures therefrom is noted, and also the serological type to which cultures from a selected single colony were found to belong.

The table of experimental results, giving the titre of each serum against the coccus examined, submitted in the full communication to the Science Committee of the British Medical Association, has been omitted from consideration of space.

It will be noted that dependence has been placed throughout on the isolation of the presumptive infecting strain of pneumococcus from sputum by culture methods. The alternative method of injection of sputum into the peritoneal cavity of a mouse and isolation of pathogenic strains by this means has not been employed, partly because it is felt that facilities for animal inoculation in this country are to a considerable extent restricted, and partly in order to ascertain how far sputal flora are representative of lung infections. That the sputum of cases of adult lobar pneumonia who acquire a massive infection of the lung is truly representative there can be no doubt; some uncertainty arises in the case of children, whose sputum, both in film and culture, differs very markedly from lobar sputum, most commonly showing a mixed flora, though usually containing pneumococci in excess. Coughing may always be induced, and a little sputum can thus be obtained, by swabbing the throat just above the upper opening of the larynx of a child suffering from bronchopneumonia.

Certain inferences appear justified from a study of the results recorded in the table.

1. The American type pneumococci are responsible for disease in this country and have a similar distribution.

2. Seeing that the Type I coccus is responsible for many typical cases of lobar pneumonia in adults, and that this infection must be widely distributed, it is remarkable that this type does not appear to cause disease in childhood. So far, the pneumococci responsible for disease in young children have been found to belong almost uniformly to Type II.

In four cases of bronchopneumonia examined *post mortem* a Type II coccus was obtained from the lungs; in the remaining eight cases from the sputum during life. From present observations it would seem that this type of coccus most frequently causes illness in children, as it has also been obtained from undoubted tissue sources—for example, empyemata or the meninges and heart's blood *post mortem*. At the same time the need for a confirmatory study of lung puncture fluid is indicated, while the sputum of normal healthy children may also repay investigation, particularly if it is found that type pneumococci are absent or relatively absent therefrom.

The passage of Type I infection from mother to child is exemplified by Cases G. and H., in which a boy, aged 12 years, developed a typical lobar pneumonia with crisis a week after his mother fell ill, her pneumonia being complicated by an empyema. On the other hand, in Cases E. and Z., a father and his son aged 4 were admitted to hospital simultaneously suffering from lobar- and bronchopneumonia respectively. A Type I coccus was isolated from the sputum of the father, a Type II from that of the child; this finding does not suggest a case-to-case infection.

In only one case, A.J., a girl aged 6 years, with empyema, has a Type I coccus been isolated from a child.

It would seem that a very different kind of susceptibility to the two types must exist in the case of children and adults, and the observed difference in the clinical aspect of pneumococcal lobar- and broncho-pneumonia is thus confirmed by the serological findings. So far as the writer is concerned this result was not anticipated.

Types of Pneumococci Occurring in Acute Infections of the Respiratory Tract.

¹ Complicated by morbus cordis.² Complicated by mitral stenosis.³ Post-diphtheritic bronchopneumonia.⁴ Primary focus, mastoid disease.⁵ General tuberculosis, terminal pneumonia.⁶ Pyopericarditis.

3. Of the other types, as already shown by American workers, Type III has a limited distribution in the upper respiratory tract in disease; it is interesting that the only specimen was derived from a mastoid abscess with pneumococcal meningitis.

4. Certain pneumococci, which there seemed every reason to believe responsible for a particular illness, did not agglutinate with the three type serums. These may possibly be referable to the heterogeneous Group IV.

Mair's modification of the bile solubility test has proved of very great value in separating off a few cocci morphologically resembling pneumococci and with similar cultural characters, but belonging to the group of salivary streptococci and on other grounds not to be regarded as belonging to the pneumococcus group.

In addition, organisms resembling pneumococci have been isolated from time to time which appear to be non-specific, although bile soluble. Such are often exceedingly hard to emulsify from plate cultures for the purpose of testing their agglutinating properties; the explanation of this physical peculiarity is not fully understood. More than sixty strains of pneumococci have been investigated in the course of the inquiry.

II.—PREPARATION OF AGGLUTINATING SERUMS BY INOCULATION OF PNEUMOCOCCI DERIVED FROM ENGLISH SOURCES.

Living cultures of the only Type III coccus obtained (Case A.N.) were unfortunately not kept, and an American Type III coccus—a stock culture obtained from Dr. St. John

Brook, Lister Institute—was utilized for the preparation of an agglutinating serum, a serum of good titre and keeping qualities being obtained from the first rabbit inoculated.

The stock Type I coccus from Dr. St. John Brook had but feeble agglutinogenic properties, but a satisfactory coccus "A" from a typical case of lobar pneumonia here has yielded good agglutinating serum. The preparation of a good Type II serum has presented very great difficulty, and caused delay and disappointment throughout the inquiry.

Of the Type II cocci investigated all are so far possessed of but feeble agglutinogenic power. Further, the wide distribution of the Type II coccus, and the variety of conditions to which pneumococci of this group give rise demands the production of a "catholic" serum of wide agglutinating scope.

Such a discovery might have been anticipated from the admittedly complex character of the Type II group. The difficulty of producing a Type II immune serum from horses has been recognized.

The principle adopted in the preparation of agglutinating serums has been the intravenous injection of standard phenolated suspensions of the selected coccus in increasing doses at intervals of forty-eight hours, and throughout only a single strain has been employed for each rabbit.

By this means satisfactory serums possessed of the property of completely agglutinating their homologous coccus, and subsequently other cocci belonging to the same group in dilutions of 1 in 80 in twenty-four hours

TABLE A.

Suspension.	Normal Serum.				"M." Serum.				"A.L." Serum.				"A.O." Serum.				"T." Serum.			
	1:20	1:40	1:80	1:160	1:20	1:40	1:80	1:160	1:20	1:40	1:80	1:160	1:20	1:40	1:80	1:160	1:20	1:40	1:80	1:160

at 55° C., were obtained in the case of a Type I strain derived from a case of typical lobar pneumonia referred to as Type I "A" and in that of the American Type III coccus from the Lister Institute.

An example of the procedure followed when preparing a rabbit, and the result, at intervals, given by its serum, may be quoted.

A young animal weighing 1,300 grams was inoculated intravenously, at interval varying from forty-eight to seventy-two hours, with five successive doses of an emulsion in 0.5 per cent. phenolized normal saline solution, increasing from 4,000 to 15,000 million Type I "A" cocci.

On the twelfth day from the beginning of the experiment a sample of the animal's serum was titrated against a standard emulsion of the homologous coccus. Complete agglutination in twenty-four hours at 55° C. occurred in dilution 1 in 10, distinct agglutination in dilution 1 in 50, a trace in 1 in 40.

Two further injections were given, the dose rising to 20,000 million cocci. At 1 of the agglutinating power of the serum was five times lower—complete agglutination in dilution 1 in 40, distinct in 1 in 80.

Doses of 15,000 million and 120,000 million cocci were repeated, and the animal, which had gained weight throughout the experiment, was finally bled out, exactly a month from the date of first inoculation. The final titration of the serum showed complete agglutination in 1 in 80, slight agglutination in 1 in 160.

The American Type II coccus proved a failure for agglutination purposes, and recourse was had to a series of Type II cocci from definite tissue sources in cases of pneumococcal infection—for example, heart's blood, empyema pus, or lung exudate *post mortem*. These cocci were referred to type by titration against an American Type II serum prepared by the Mulford Company, Philadelphia. The strains employed are derived from the cases whose cipher they bear; the clinical features of each are noted in the table on p. 261.

The Case "I" Type II serum at first feebly agglutinated American Type II coccus, but, on keeping, this action became limited to its homologous coccus.

Case "M" and Case "J" cocci were next tried but without success, the titre obtained by the Case "J" serum after sixteen injections over a period of six weeks being only 1 in 10.

It was thought that the animals employed might be in themselves poor agglutinin producers, but a result similar to the above was again obtained after repeated injection. In view of this lack of success the effect of unheated emulsion of cocci killed by the addition of 0.5 per cent. phenol and incubation at 37° was next tried, a rapid method of five injections at intervals of forty-eight hours being employed and the animal then bled out.

The titres of the two serums obtained were respectively:

	1:10	1:20	1:40	1:80
Case AL. ...	++	++	+	(+)
Case M. ...	+	+	(+)	-

++ = Complete agglutination, clear fluid.
+ = Distinct agglutination, fluid not clear.
(+) = Slight agglutination.
tr = Trace only.

Encouraged by the improved titre of the "A.L." serum, two other rabbits were inoculated with the Case "A.O." and Case "J." cocci, as before unheated but killed by phenol.

A sample of the blood of each rabbit taken from the ear prior to bleeding out yielded a serum with the following titre in twenty-four hours:

	1:10	1:20	1:40	1:80
Case J. ...	++	++	++	++
Case A.O. ...	++	++	++	++

Three days later each of the four serums was titrated against its homologous coccus and the other cocci of the group, with the result shown in Table A. Some doubt was felt as to the accuracy of the readings owing to the fact that somewhat indifferent suspensions of cocci with tendency to auto-precipitation were employed and the experiment was therefore repeated a fortnight later, with the following result:

TABLE B.

Coccus.	T.			AL.			AO.			M.		
	1:10	1:20	1:40	1:10	1:20	1:40	1:10	1:20	1:40	1:10	1:20	1:40
J. ...	(+)	+	tr	(+)	-	-	(+)	tr	-	-	-	-
AL. ...	-	-	-	(+)	(+)	-	(+)	+	-	-	-	-
AO. ...	-	-	-	-	-	-	++	+	-	-	-	-
M. ...	-	-	-	(+)	-	-	-	-	-	(+)	-	-
A. ...	(+)	tr	-	-	-	-	-	-	-	-	-	-

No agglutination with normal serum control.

Rapid deterioration of all serums had obviously occurred, the reason for which has not yet been clearly defined; these serums were necessarily discounted and two more rabbits prepared against the AL. and M. cocci.

The AL. serum agglutinated its homologous coccus in dilution 1 in 20, and was thereupon tested against a group of cocci previously typed by the Mulford II serum to confirm the reactions of this serum. The result, Table C, indicated that the AL. serum was not only a feeble agglutinator, but insufficiently "catholic" as regards the Type II group.

TABLE C.

Type II Cocci.	AL. Serum.		Normal Serum.	Type II Cocci.	AL. Serum.		Normal Serum.
	1:10	1:20			1:10	1:20	
AL. ...	+	(+)	-	AA. ...	(+)	(+)	tr
AY. ...	(+)	-	-	AB. ...	+	(+)	tr
Y. ...	-	-	-	AM. ...	(+)	tr	+
Z. ...	+	+	+	"B," Type I	-	-	-

* Poor suspension.

+ Control.

Meanwhile it was necessary to identify the type of a number of cocci which had been collected. A small quantity of Type II serum from the Rockefeller Institute became available from the pathological department, Charing Cross Hospital, and was tested against standard emulsions to ascertain its agglutinating properties. The serum proved so active that it agglutinated not only selected Type II cocci in all dilutions up to 1 in 80 but also reacted with a Type I and Type III coccus in dilution of 1 in 10 and 1 in 20.

This cross-agglutination was found to be eliminated by using the serum in higher dilutions only. Finally, the serum was employed with satisfactory results in dilutions of 1 in 40, 1 in 80 and 1 in 160.

The problem presented by the preparation of a Type I serum cannot at present be considered solved. The remains to discover by repeated trial a Type II coccus of good agglutination power and thoroughly representative of the group. Or, failing this, to investigate further the conditions which determine the production of agglutinin against the pneumococcus in the rabbit and lead deterioration of agglutinin in serums when kept.

In conclusion, it may be said that the Type I pneumococcus is the most clear-cut and important of all. It is responsible for many of the severest cases here, while

American investigators have shown that Type I therapeutic serum has an appreciable effect in reducing mortality from lobar pneumonia; the serums prepared from Types II and III being up to the present far less successful.

In view of this practical aspect of the observations recorded in this report, it was necessary to determine whether the English strains of Type I cocci, identical with the American type on simple agglutination, are also indistinguishable when submitted to what is perhaps the most specific test available, the absorption of agglutinin.

The cocci compared in this respect were Type I American, English Type I "A," Type I "B" with Type II "M" as control. The serum used was the Type I "A," prepared as described.

The experimental procedure was as follows:

1 c.cm. of dilution 1 in 5 "A" serum was put up against equal amounts of suspensions containing 4,000 million per c.cm. of each of the above cocci.

Conditions.—Two hours in the water-bath at 37° C. Tubes then centrifuged and the supernatant fluid titrated against the Type I "A" coccus homologous to the serum.

Absorption Experiment.—Type I "A" serum absorbed with Type I "A" coccus, Type I, U.S.A. coccus, Type I "B" coccus, Type II "M" (control) coccus.

Result after Saturation V, Type I Coccus "A."

	Dilutions.			
	1:20	1:40	1:80	1:160
Control saline	++	++	++	(+)
Control Type II "M"	++	++	++	(+)
Serum saturated with Type I "A" ...	+	(+)	—	—
Type I, U.S.A.	+	(+)	—	—
Type I "B"	+	(+)	—	—

Thus while Type II "M" completely failed to reduce the Type I agglutinin, the Type I cocci all caused its reduction by about three quarters as shown in the accompanying table. In view of this result, there is no room for doubt that the two specimens of Type I coccus isolated from cases of typical lobar pneumonia in this country are identical with the stock specimen of Type I coccus obtained from America.

With a view to preparing Type I serum for therapeutic use, cultures of the organisms isolated from English cases have been forwarded to Dr. E. G. Murray, who is working at the Field Laboratories, Cambridge, on behalf of the Medical Research Council, at the production of therapeutic serum.

Throughout the inquiry I have been constantly indebted to the active assistance, encouragement, and advice of Dr. Mervyn H. Gordon, bacteriologist to St. Bartholomew's Hospital, and of his assistant, Mr. T. Heggerty, to both of whom I express my grateful thanks.

EXOMPHALOS, OR HERNIA INTO THE UMBILICAL CORD.

BY

ROBERT TENNENT, M.B., CH.B.GLAS., F.R.C.S.ED.,
ASSISTANT SURGEON, ROYAL HOSPITAL FOR SICK CHILDREN,
AND JUNIOR ASSISTANT SURGEON, VICTORIA
INFIRMARY, GLASGOW.

The condition of exomphalos, although somewhat rare, is of considerable interest, both from the point of view of origin and that of treatment.

It may present an abnormality of such extreme degree that the greater part of the abdominal organs are contained in a sac at the umbilical attachment of the cord or near that situation; but more commonly it consists of a globular swelling of about the size of a Tangerine orange. The former extreme cases are beyond surgical aid, but the more moderate degrees are eminently suitable for operation.

The literature, although fairly copious, contains few accounts of successful surgical treatment, the reason generally being that the cases were seen, or the operation performed, too late, when either infection or obstruction with gangrene of the contents of the sac had taken place. The appended cases, illustrative of the success of immediate operation, occurred in Mr. MacLennan's wards at the Royal Hospital for Sick Children, Glasgow.

Definition.—Exomphalos has been defined by Ballantyne¹ as a true hernia of abdominal contents into the umbilical cord. It is distinct, he says, from the deformity associated with a greater defect in the abdominal wall than merely in the neighbourhood of the attachment of the cord. To this condition he gives the name gastroschisis. A less pronounced form of this abnormality has been described by Nicaise as "amniotic umbilicus," and consists of a deficiency of skin around the umbilicus, the deficient space being covered by amnion from the cord. In a recent article Friend² describes a case of exomphalos and prefers the name of amniotic hernia, quoting Moschowitz³ in support of the view that the term "hernia into the cord" is a misnomer. The undermentioned cases have all been clearly of the nature of hernia into the substance of the cord, and conform to Ballantyne's definition. Accepting this definition, it might at first appear that all cases of exomphalos would be amenable to early treatment, whereas cases of gastroschisis are beyond relief. This, however, is not so, for some of these hernias, although having but a narrow communication with the abdominal cavity, have nevertheless contained such proportions of the abdominal, and even thoracic, organs as to render replacement impossible.

Frequency.—Exomphalos is estimated by various authors to occur in from 1 in 2,000 births to 1 in 6,000 births.

Clinical Characteristics.—The abnormality usually takes the form of a globular, asymmetrical swelling situated at the abdominal attachment of the cord and extending into its substance. Sometimes there is a constriction between the swelling and the abdomen. In such a case a serious accident might happen, as in the case described by Victor Bonney,⁴ and quoted by Friend,² where the practitioner removed the hernial sac and its intestinal contents, consisting of small intestine, during the process of ligature and division of the cord at birth. In size it varies from a walnut to a large apple, but is commonly of an intermediate size. The coverings of a light grey colour are often quite transparent, and admit of inspection of the contents of the sac. In other cases the colour is darker and the sac opaque. The covering consists of three layers, namely, amnion, Wharton's jelly, and peritoneum, the former two constituents tapering at the summit of the swelling and passing along the cord. Occasionally the skin of the abdominal wall is continued some distance on to the swelling and forms a funnel-like cup into which the swelling fits. The swelling contains usually some part of the intestinal tract and—as would be expected—not infrequently a Meckel's diverticulum. In two of the cases the caecum and appendix were found in the sac, and in both the caecum had a well-marked mesentery. Rarely can the contents be reduced into the abdomen, and more often there is obstruction to the passage of bowel contents or even a complete strangulation of bowel. If treatment is delayed one of two conditions speedily causes the death of the child: It succumbs to intestinal obstruction, or the covering membranes are torn or slough off and peritonitis ends the case.

Treatment.

Operation at the earliest possible moment after birth is the only successful method. This statement is apparently at variance with some textbook teaching on the subject. One author⁵ states:

"Possibly in some of these less pronounced cases a radical operation may with safety be undertaken, especially if the infant has reached a few months of age."

And again:

"In certain favourable cases, where the child attains an age which will render operation justifiable, say six months or more, removal of the sac wall and suture of the edges of the gap may lead to a permanent cure."

Otherwise treatment would consist in the endeavour to prevent sepsis by appropriate dressings. Now, in the presence of the usual thin tissue-paper-like covering this is

an attainment wellnigh impossible, and in addition there is frequently the complication of obstruction. The obvious aim would appear to be the safe return of the contents to the abdomen at once. It is difficult to understand the need for postponement of operation "to a favourable age, six months or more," for all our experience goes to prove that infants stand the operation for this as well as ordinary hernia very well. This view is held by the French surgeons generally. Jaboulay and Patel,¹¹ quoting many authors in support, urge operation at once, the danger of infection being so great. At one time, on account of bad operative results, the Germans⁶ relied on the application of an alcoholic compress bandaged firmly over the umbilicus, but this treatment is now permissible only in deformities too large for operation.

Operation consists in opening the sac, separating it from the contents, and returning the contents if healthy to the abdomen. The vessels of the cord are carefully ligated at the neck of the sac. In late cases gangrenous bowel may be met with and the outlook is hopeless. When a Meckel's diverticulum is encountered it should be removed. Occasionally there is difficulty with adhesions, and when the hernia is very large the replacement of all the contents may be exceedingly difficult. An appendicostomy¹² can with advantage and without difficulty be done. The appendix is brought out at a small stab wound made on a piece of gauze held within the abdomen close to the anterior superior iliac spine. This is of benefit in relieving distension and in the administration of fluid by the colon in after-treatment.

ILLUSTRATIVE CASES.

Case 1.—Baby W., aged 2 days. Admitted with definite signs of intestinal obstruction. There was a swelling at the base of the cord about the size of a small orange; its coverings were thin and transparent, and somewhat soiled and septic-looking; the bowel contents were clearly visible through the coverings. On opening the membrane the caecum and appendix and part of the ileum were found in the sac. They were folded over, producing complete obstruction (Fig. 1). They were returned to the abdomen and appendicostomy done as described above. The sac was removed low down, the peritoneal edges and the rectal sheaths brought together with sutures and the skin sutured. Salines were given by the appendix opening and the child made a good recovery. The appendicostomy was closed at the end of fourteen days.

FIG. 1.—A, Skin. B, Fused layers of amnion, Wharton's jelly and peritoneum. C, Umbilical cord. D, Parietal peritoneum. E, Fibres from rectus sheath. F, Ileum. Contents: Caecum and appendix twisted on ileum.

Case 2.—Baby McC. Admitted one hour after birth, presented an irreducible swelling of the size of an orange at the base of the cord. The sac was opened and a greatly thickened and distended Meckel's diverticulum was exposed and removed. The operation was completed, as above, without appendicostomy—there being no indication for it—and the recovery was uneventful (Fig. 2).

FIG. 2.—A, Skin forming funnel-like process at base of swelling (Case II). B, Fused layers forming covering of swelling. C, Umbilical cord. D, Parietal peritoneum. E, Rectus muscle. F, Ileum. Contents: Meckel's diverticulum.

Case 3.—Baby S., aged 2 days. This case illustrates the result of delay. There was a small opening at the umbilicus through which the greater part of the bowels had herniated. The sac, stretched thin, had given way, and coils of bowel were quite exposed and had pieces of cotton-wool dressing adherent when the child was admitted. The possibility is that the sac was

torn at delivery. The exposed intestines were red and inflamed, the peritoneum being obviously infected. A closed Meckel diverticulum was adherent to the remains of the sac. Operation was undertaken, but, as was expected, death took place later. At necropsy generalized peritonitis, patent ductus arteriosus and patent foramen ovale were found.

FIG. 3.—The "polypus" split in two. A, Skin. B, Wharton's jelly. C, Peritoneal sac. D, Pedicle.

Case 5.—Baby J., aged 4 months' illustrates an almost spontaneous cure of a small exomphalos. The child had a small rounded pedunculated swelling at the umbilicus—the so-called umbilical polypus. On removing this, a small peritoneal sac was found in the middle of it (Fig. 3). The outer layer of the swelling had become covered with epithelium from skin.

Etiology.

It would appear that three main groups of factors require consideration. They are: possible antenatal conditions, developmental causes, and defects in function.

In the first group abnormality in the foetal position was thought to be the cause. Sir James Simpson⁷ stated that such cases were nearly always abdominal presentations. This lends support to another theory, that the position of lordosis in the foetus may be a cause, but the origin of such a lordosis falls into the second developmental group.

Ballantyne states that hydramnios may be a cause, and there is increasing evidence that hydramnios is a common concomitant of other foetal malformations.

Lordosis in the foetus may be caused by a pull on the omphalo-intestinal duct, and Bryce⁸ suggests that a retroflexion of the trunk of the embryo may result from defective development of the allantoic stalk and hind gut interfering with the curling of the tail end of the embryo. This view is favoured by Aschoff.⁹

An unduly short cord of itself might reasonably be a factor by causing stretching, and in extreme cases the effects of some such stretching are evident in the marked involvement and alteration of shape of the chest and solid organs. Similarly a persistent omphalo-vitelline duct may cause stretching, and it is interesting to note that one author¹⁰ states that such tension may be so marked in the embryo as to interfere with the downward growth of the rectum and hence cause imperforate anus. In this connexion it may be noted that the vitelline duct persisted in two of the four cases.

It seems unlikely that a defect in the skin development is a factor, for there was even an excess of skin in some cases. A defect in the development of the mesoblastic layer of the abdominal wall is more likely. A general enlargement of the abdominal viscera might cause a failure in the closure of the abdomen, but in none of the cases could such enlargement be made out. Moreover, a case has been recorded where the abdominal wall closed and nipped off a loop of jejunum (Abelfeld). This loop would most likely be the normal umbilical loop of intestine, which is present in the commencement of the cord up to the third month of intrauterine life (Bolk).¹¹

This leads to a consideration of possible functional defects. Whilst the cutting off of the umbilical loop may have been due to excessively rapid development of the mesoblastic layer of the abdominal wall, the converse could equally take place. Thus, a defect in the development of mesoblast might result in a patency. Now, a defect in function of the mesoblast—that is, of the recti muscles—could act in the same way. This functional defect could originate in trophic, nerve or toxic irregularities. The condition is distinctly analogous to that of spina bifida, and this was long ago considered due to a dropsical condition in the foetus, producing a hernia of the meninges by interfering especially with the growth of mesoblast. This dropsy might originate in foetal heart disease, and in one of our cases there was a marked foetal heart disease. On the other hand, such cardiac weakness could conceivably arise from toxins received from a diseased maternal uterus. It was suggested in a recent review¹² of the subject of spina bifida that uterine conditions in the mother required closer investigation as possible causes of that malformation. The same applies to exomphalos, but, unfortunately, no details were got with reference to our cases.

Finally, we fall back on the trophic function, irregularity in the controlling mechanism of which may account for

almost any congenital deformity. In this connexion, Hertwig's¹² work is of great interest, for he succeeded, by applying chemical solutions to the ora of fish and amphibians, in producing many deformities, including spina bifida. A purely chemical and metabolic factor may therefore be at work.

There seems little need now for the consideration of the disconformant amniotic band theory as a cause of any such deformity.

Conclusions.

1. The cause of exomphalos is most likely a defect in the development or function of the mesoblastic layer of the abdominal wall.

2. Treatment, to be successful, must be immediate and consists of open operation.

To my chief, Mr. Alex. MacLennan, I am indebted, not only for permission to publish these cases, but for much valued help and suggestion.

THE CURE OF HAEMORRHOIDS WITHOUT OPERATION.

BY

J. C. LYTH, M.B., B.S. LOND.

I am somewhat diffident about placing my views on this subject before the readers of the BRITISH MEDICAL JOURNAL; but it is a journal which is read chiefly by general practitioners, and it may be helpful for general practitioners sometimes to read what one of their number thinks, even though it be heresy he preaches.

My text is that operation for haemorrhoids is not always successful, is usually unnecessary, and is rarely justifiable.

I have drawn no distinction between internal and external haemorrhoids, because I think most practitioners will agree with me that such a distinction is purely artificial. Varices exist inside the anus; some are forced down in defaecation, and fail to get back before the mucous membrane covering them is gripped by the sphincter. In the first instance they are internal; after coming down they are external. If they can be returned with the aid of providence and a little coaxing, they become internal again until next time. Finally, they come down for good, and cannot be returned.

Up to a point the presence of piles outside the anus may be taken as an indication of the presence of more piles inside ready to come down. An author recently stated the limit in number of potential piles to be eight, that being the number of venous loops inside the anus. It is certainly a fairly large number, and in practice I suppose none of us have found the whole eight possible piles outside, with consequently no more piles, or possibility of piles, inside.

The critical period is when a pile is changing, or has recently changed, from inside to outside the anus. So long as it is inside and remains always inside (even during defaecation), it does little harm. When it prolapses during defaecation, and when it first comes out for good, it causes all the pain, haemorrhage, and irritation, and is liable to thrombosis and suppuration. Later, after a varying but usually considerable period, it becomes covered with squamous epithelium, and therefore insensitive, and small, and is no more than an inoffensive tag of skin, which, with reasonable cleanliness, need cause no trouble. All this may be rather crude pathology, but it is clinically, I think, a fair summary of the sequence of events.

Operation is not always successful. The usual operation removes the piles which are outside, and perhaps the more prominent of those inside. In regard to this—analogously with those of the leg—it must be remembered how remark-

ably varices may disappear under the conditions of anaesthesia and an alteration in the position of the body. Note, too, what a difference there is between the conditions of straining and prolapse of defaecation and those of the lithotomy position.

The operator at the same time puts the sphincter out of action for the time being, and gives the patient very good advice as to diet, exercise, and aperients. To my mind, if the piles do not "recur"—or, to be more accurate, if more piles do not come down—it is likely to be as much due to the advice of the operator, impressed on the patient's mind by the expense, trouble, and pain of the operation, as to anything done at the operation. The author to whom I have referred admits this, but suggests a very much more radical operation, amounting almost to a resection of the mucous membrane lining the whole canal of the anus and lower rectum. I cannot speak to the results of this, but it is not the operation for piles usually undertaken, and I have seen certainly one case of most troublesome stricture resulting from a much less sweeping operation than this.

The usual operation for piles is not a dangerous one; but it is an operation, and as such, from the point of view of the patient and the conscientious practitioner, to be avoided if possible; it is painful and it is not certain to cure.

Now for the alternative: The usual palliatives—ung. hamamelidis, ung. gallae cum opio, etc.—are no more than palliative. They to some extent relieve pain, but do little to stop the bleeding and nasty mucous discharge. I consider them only fit for use during an attack of thrombosis—after the worst has been got over with fomentations—and also if it is essential that a patient should go about his work after a recent defaecation.

But there is a means of curing piles, in the sense that they can be made entirely innocuous. It is a question of reducing from a year or two to a month or two the period necessary to change a turgid mucus covered and tender varix into a skin-covered excrescence and preventing the piles still inside the anus from coming out.

I have seen the application of calomel powder recommended and have tried it. It is useful, but calamine powder is much more so. Calomel is a trifle irritating, but calamine is soothing and is astringent as well. But the mere instruction to apply calamine will do little good.

Suppose a bad case, with a ring of prolapsed piles surrounding the anus, some perhaps denuded of epithelium, intensely and agonizingly tender, bleeding on defaecation, and continually discharging blood-stained mucus, which stains the linen and renders the patient's life a burden. The following plan will change the picture:

1. The bowels must be moved the last thing at night before retiring. It may be difficult to alter the usual habit of morning defaecation, but it is essential, and can be contrived by suitable aperients.

2. It is hardly necessary to say the bowels must be moved every night, but a loose action must be avoided. Even a slight degree of constipation so long as a nightly action of the bowels is secured, while not so good as an easy action, is infinitely preferable to the slightest diarrhoea. This means care and discretion in the use of aperients.

3. After the motion, and after gentle sponging with tepid water, calamine powder is to be applied in the following way: it is to be freely and thickly placed (not merely sprinkled) on a sanitary wool and gauze pad. It is cheap enough, but it need not be wastefully used if care be taken that there is a sufficient quantity (say a couple of teaspoonfuls) on the exact part of the pad which will remain in contact with the piles when the tapes are tied round the waist. It is necessary that the pad should be pulled firmly up into position.

If there is much discharge the pad should be changed in the morning and fresh calamine applied. If at first there is too much discomfort during the day, it is permissible to substitute ointment—for example, hamamelis—thickly applied on the pad worn during the day. But it must be explained that this is a step which somewhat retards results and does no permanent good. If the patient has the misfortune to have the bowels moved in the morning or during the day he will almost certainly have to be allowed to use ointment on the pad which he then applies, to be changed for the powder at night.

It will be found that after a time, probably not more than a fortnight or three weeks even in the bad case, no

have supposed, the piles will be sufficiently shrunken and dried and painless by the morning for the daily pad to be dispensed with, unless the misfortune alluded to occurs. Meanwhile, those of the piles normally inside, but which prolapse on defaecation, are coming into contact with the calamine before their gradual return during the night, and, subjected to its astringent action, are becoming smaller and less sensitive.

After a further lapse of two or three weeks the patient will find that, although there may be some prolapse of the internal piles on defaecation, this is so readily reduced, or reduces itself on attaining the recumbent position, that he can begin to leave off the pad at night, unless he has been either too constipated or too relaxed. He is then in a fair way to being cured. He must always have his bowels moved at night, and he is wise to have calamine and a pad available. It is, in my experience, quite futile to attempt to apply the powder in any other way than that described.

The habit of a nocturnal action of the bowels, which allows the immediate assumption for many hours of the recumbent posture, will go far to prevent any further prolapse of such piles as remain inside the anus; and I believe that in this way it will ultimately cause their reduction in size; because it is the persistence of the partial prolapse which normally occurs in defaecation which has gone far to bring them to their condition at the beginning of treatment. I assume that the haemorrhoids are not due to any direct obstruction to the portal circulation or to any local cause such as pregnancy or growth; and that exercise and limited diet will be advised.

With this alternative to operation—an alternative which is inexpensive, which entails no danger, no interference with business, and which is likely to be permanently successful—I think I am justified in my heretical proposition that operation is usually unnecessary and rarely justifiable. The remedy is almost as simple as dipping seven times in Jordan; and for that reason, doubtless, there will be those who prefer that the surgeon should "strike his hand over the place" by way of operation. Likewise, there will be the advocates of Abana and Pharpar in the shape of ointments and lotions. None the less, I hope there will be others who will emulate Naaman and decide to give this method a trial, for I have had such excellent results with it in the past three years that personally I shall advise operation only as the last resort.

RESECTION OF INTESTINE FOR ACUTE INTUSSUSCEPTION: TWO CASES OF RECOVERY.

BY

A. H. SOUTHAM, M.A., M.Ch.Oxon., F.R.C.S.Eng.,
SENIOR SURGICAL OFFICER, MANCHESTER ROYAL INFIRMARY;

AND

C. H. CRAWSHAW, B.Ch.Camb., F.R.C.S.Eng.,
JUNIOR SURGICAL OFFICER, MANCHESTER ROYAL INFIRMARY.

THE published results of enterectomy in cases of acute intussusception in infants show such a high mortality that the following cases, each of a rather unusual type, may be of interest.

Rowlands and Turner¹ quote Gibson, who says that in his collection of 1,000 cases he found only one case of recovery after resection for this condition. In an earlier collection of 239 cases there was no recovery from irreducible intussusception in a patient under seven years. Moynihan² quotes A. E. J. Barker, who says he had never seen a recovery after resection in a gangrenous case, and never expected to see it. Fagge³ reported 5 cases that were irreducible and all were fatal.

CASE I.

John C., aged 3 years, was admitted to the Manchester Royal Infirmary on December 11th, 1919. His mother stated that he had not been well for a week. He had been vomiting continually, and his bowels had not been moved for five or six days. No blood had been passed as far as she knew. The child looked ill, the temperature was subnormal and the pulse 130. The abdomen was very distended, and no tumour was palpable. On rectal examination a little blood and mucus remained on the finger-stall.

A diagnosis of intussusception was made, and laparotomy immediately carried out. Owing to the child's poor condition,

Mr. K. B. Pinson kindly gave gas and oxygen anaesthesia. The abdomen was opened by a right rectus incision, and a tumour, extending to the splenic flexure, was discovered. This was reduced easily at first by expression. After the gut had been reduced through the ileo caecal valve, it was seen to be a double intussusception, an ileo caecal being superimposed upon an enteric intussusception. The terminal portion of the ileum was found to be in a bad condition; it was irreducible, and there were several gangrenous patches which had perforated during the attempt at reduction. It was therefore decided to resect this portion of the ileum. This was rapidly carried out, and an end-to-end anastomosis performed between the cut ends, two layers of linen thread being used for the suture line. The portion of gut excised measured 10 in., and there were five gangrenous patches involving all the coats present. The abdominal wall was closed with through and through sutures of silkworm gut. The operation lasted twenty five minutes.

Post anaesthetic vomiting was completely absent and the child was able to take fluids immediately, shock being very little in evidence. The bowels moved the following day and each day subsequently.

Apart from a little sepsis in the wound the child made an uninterrupted recovery, and was discharged from hospital on January 13th, 1920. We have seen the boy several times since; he is in excellent health, and has had no further abdominal trouble.

CASE II.

M. R., aged 6 months, was admitted to the Manchester Royal Infirmary on December 13th, 1919. She was thin, cold, clammy and collapsed; about 7 in. of intestine carefully wrapped in newspaper protruded from the anus. The diagnosis from prolapse was not difficult, and there had been symptoms of intussusception for about twelve hours before the intestine had appeared externally.

When first seen the last two or three inches of protruded gut were very oedematous, dark purple and gangrenous. The swelling caused by the oedema quite prevented the gut from being returned through the anus, consequently the only procedure possible was to resect the intestine externally and push back the stump. This was done in the manner often known as Jessett's operation, with this difference, there being no ensheathing layer, the time usually occupied in opening and closing this was saved and the operation simplified.

The gut was pulled out still further and clamped in the healthy part thus made accessible, about 2 in. from the anus and about 7 in. from the gangrenous apex. The part distal to the clamp was now removed one inch from the clamp, and the entering (inner) layer of the intussusception sutured with continuous thread to the encircling returning layer. Only one row of sutures was applied, taking up all the coats of intestine. Some difficulty was experienced with the mesentery which was between the two layers, and made a large thick mass, and also with the disparity between the diameters of the two concentric circles of intestine. The stump was now easily reducible through the anus, and was kept in position for twelve hours by a pad of gauze on a large rubber tube in the anal canal and held there by a perineal bandage. No anaesthetic was used, the patient being practically moribund and quite motionless throughout the operation.

The point of anastomosis could afterwards be felt high up on the left side with the finger in the rectum, but there was no tendency to a recurrence of the condition. There was no post-operative vomiting, fluids were administered at once and recovery was quite uneventful. The child was seen five months afterwards; she was then quite fat and apparently in perfect health.

On examination of the part removed, the ileo caecal valve and appendix were found at the apex—that is, the intussusception was of the ileo caecal type. About 6 in. of intussusception were resected, which corresponded roughly to the whole of the caecum, ascending colon and part of the transverse colon, with an equivalent length of included small intestine.

In both these cases the intestine was gangrenous, and an extensive resection was necessary, but complete and uneventful recoveries followed.

The successful issue was, we consider, to a great extent due to the measures taken to safeguard the patient from the effects of shock. We suggest that shock can be considerably reduced, and the outlook therefore improved, by the following expedients:

1. *Speed in operating is essential.* Everything should be ready to hand, and the closure of the laparotomy wound should be carried out by through-and-through sutures. Suture in layers is unnecessary and expensive in time.
2. *The body heat should be preserved by bandaging the child in a suit of gamgee and the theatre maintained as warm as possible.*
3. *The anaesthetic appears closely related to the amount of shock present.* In one of our cases this was minimized by using gas and oxygen, whilst in the other no anaesthetic was used.

Shock further depends on the *water starvation* resulting from the previous vomiting and loss of fluid. In both the

ve cases post-anaesthetic vomiting was entirely sent, and fluids were given and retained immediately operation was completed. The body nutrition therefore commenced at the earliest possible moment. The chief difference between these two cases was that one the abdomen was opened, whilst in the other it was not. It is suggested that the shock consequent upon opening the abdomen may be considerably reduced by employing the above methods, and the prognosis, therefore, is permanently improved.

COMPLETE HEART-BLOCK IN A CASE OF DIPHTHERIA.

BY

R. CLAYTON ALLEN, M.R.C.S., L.R.C.P., D.P.H.

THIS case, admitted under my care in the Belper Isolation Hospital, was apparently doing quite well, until the seventh day of disease, when heart block suddenly developed.

The notes are as follows:

M. L., a girl aged 17 years, was admitted to the hospital on September 1st, 1920. She was taken ill on August 29th with a feeling of malaise and a sore throat, and the following day was seen by her doctor, who administered 4,000 units of antitoxin, followed by a further 2,000 on the following day. On admission to hospital the tonsils and uvula were seen to be covered with the diphtheritic membrane. Neck was much swollen. Temperature 120; slight difficulty in swallowing. Brandy 4 oz. swabbed and sprayed to the neck. Patient of September 3rd was very comfortable. Temperature 99, respirations 20, pulse 95, when brandy was stopped; the improvement continued until 5 p.m. the following day, when the patient suddenly had a "convulsion"; marked cyanosis, and pulse became imperceptible; temperature subnormal. Brandy 4 oz. w.

she was breathing
 pulse 26, temperature
 on auscultation the
 rate, whilst over the
 12 per minute. Liq.

I saw quietly 95 6. ventric aricled stych in was ordered four hourly, and brandy 4 oz. four-hourly; oxygen to be administered five minutes every quarter of an hour, and a mustard plaster placed over cardiac region. I saw the patient again at 8.30 p.m., when she seemed quite comfortable; still cyanosed, and the heart in the same condition as before. I saw her again at 11 p.m. in consultation with Dr. Barber of Derby.

About 1 a.m. on September 5th she had another slight convulsion, after which the patient slept until 7 a.m., when the pulse was 55, temperature 97°, respirations 18. At 10 a.m. she had a further convulsion and became more cyanosed; temperature 97°, pulse 22, respirations 18. The oxygen was still continued, and 1 c.cm. of pituitrin was administered subcutaneously.

During the day the patient did not improve, took nourishment badly, and had incontinence of urine. A further cubic centimetre of pituitrin given at 2 p.m. The patient remained listless until 8.45 a.m. September 6th, when she vomited; this was followed by a convulsion. Temperature 96.8°, respirations 16; pulse imperceptible, but the ventric could be heard 22 per minute, and the patient complained of acute pain over the cardiac region. Death took place at 11.20 a.m. The urine showed a marked cloud of albumin the whole time the patient was in hospital.

Note by Dr. HUGH BARBER.

Myocardial poisoning is a common event in diphtheria, and may be accepted without doubt as the cause of death in this case, but from the clinical point of view it was an unusual form of heart failure.

When seen by both of us together there was little distress, the radial pulse was strong and regular, 26 beats to the minute; the heart was not dilated, the cardiac impulse was vigorous, rate 26, with clear normal sounds. Over the base of the heart muffled sounds could be heard suggesting auricular beats twice as rapid as the ventricular. It was not possible to take a jugular tracing to prove the diagnosis, but complete heart block due to poisoning of the auriculo ventricular bundle may, we think, be taken for granted. The case presented unusual difficulties both in treatment and prognosis.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

TORSION OF THE TESTIS IN AN INFANT.

THE infant was born on February 13th, 1920, and on the 18th the nurse noticed some swelling of the right side of the scrotum. This swelling increased, and on February 21st I saw the infant, with Dr. L. Gifford Nash of Turvey, Beds. There was no pain, and the baby seemed quite well, and was taking his food. The right side of the scrotum was swollen, the skin was blue, and the superficial veins dilated. The skin was adherent to the testis, which was much swollen and tender. The cord was thickened as high as the external ring, where there appeared to be a small nodule or swelling. I diagnosed a torsion of the testis and cord, and advised operation, which was performed on February 22nd.

An incision was made into the inflamed tissues of the scrotum, the separate layers of which were indistinguishable, until the cavity of the tunica vaginalis was reached and a thick yellow fluid gushed out. The testicle, purple in colour, appeared lying at the bottom of the tunica vaginalis. The cord was tied high up in the scrotum and the testis removed. No definite torsion of the cord was seen, but it was not exposed as high as the external abdominal ring. The infant made a good recovery.

The specimen removed was sent to Mr. S. G. Shattock, at the Royal College of Surgeons, who reported: "There is intense congestion of the tunica vaginalis and tunica albuginea. On dividing the testis there are seen superficial extravasations in its substance. I think that your first impression—namely, that the condition was caused by torsion—is correct."

Since I first reported a case of torsion of the testis (*BRITISH MEDICAL JOURNAL*, 1891, vol. 1, p. 1225) many cases have been reported. A few cases have been recorded in infants. The earliest on record is that reported by Taylor (*BRITISH MEDICAL JOURNAL*, 1897, vol. 1, p. 458), which was operated on at the age of two days. Rigby and Howard (*Lancet*, May 25th, 1907) reported one at seven months. Edington (*Lancet*, June 25th, 1904) also reported one at seven months. Dowden (*Scottish Med. and Surg. Journ.*, September, 1901) reported cases at five and fourteen months. Including the present case six have been recorded within fourteen months, which appears to be an unusual proportion. These cases show the liability of torsion occurring in infants, and that it is probably the only cause of acute inflammatory swelling in the scrotum in early life.

Bedford.

W. GIFFORD NASH, F.R.C.S.

TREATMENT OF LOCAL LEISHMANIASIS.

WITH regard to recent discussions on the best local treatment for local leishmaniasis (Delhi sores, Baghdad boils), I should like to mention the treatment suggested by Surgeon-General Patterson, when Principal Medical Officer of the Aldershot District, to me, when I was in charge of the surgical wards of the Cambridge Hospital, Aldershot. A soldier had recently returned from India suffering from an intractable form of Delhi sore on the left wrist, which I had treated by scraping away the granulation tissue, followed by applications of solid silver nitrate, but with little progress as to healing. The treatment recommended to me was to scrape and clean the sore again thoroughly, and lightly apply solid caustic potash and dress. After one application the granulation tissue came away, and the sore healed as a clean healthy ulcer, and there was no return, either local or general. I gather that our present treatments are not satisfactory. I therefore put forward this method for trial by specialists and others.

London

E. J. ERSKINE RISK, Col. A.M.S.(ret.),
 Ex Commandant, R.A.M.C. College

IN Java 358 cases of plague occurred last December, all of which were fatal.

PROFESSOR J. LEPIEVE has been elected Dean of the Lyons Faculty of Medicine in succession to Dr. Hugonnet.

DR. PIERRE BAZZ has been elected member of the Section of Medicine and Surgery of the Académie des Sciences in place of the late Professor Guyon.

Reports of Societies.

EXOPHTHALMIC GOITRE.

A COMBINED meeting of the Clinical Section of the Royal Society of Medicine with the Sections of Medicine and Surgery was held on February 11th, for a general discussion on Graves's disease. Sir ANTHONY BOWLY, President of the Clinical Section, took the chair, and the attendance was so large that the usual meeting room had to be exchanged at the last moment for the Barnes Hall, which was crowded out. About twenty members of the Sections signified their desire to participate, and after the discussion had been opened on both the surgical and medical sides, it was adjourned to February 25th.

Surgical Treatment: Indications and Contraindications.

Dr. HECTOR MACKENZIE said that in former discussions he had expressed scepticism with regard to surgical treatment of exophthalmic goitre, believing operation to be attended with undue risk. Ten years ago, at a similar discussion, a paper was contributed by Mr. T. P. Dunhill, of Melbourne, who reported results of surgical treatment so much superior to anything the speaker had seen in this country that he had grave doubts whether the cases were of the same class. These operations in Australia had been done under local anaesthesia, whereas all the cases of which he had personal experience were done under general anaesthesia. In 1915 he had under his care a patient who, after eighteen months' treatment, showed no obvious improvement. Mr. Dunhill, who had come over with the Australian Expeditionary Force, was consulted, and did partial thyroidectomy under local anaesthesia. The operation passed off perfectly: when it was half-way through the patient asked when it was going to begin! The effects of the operation were immediate, and the patient was better in every way. A colleague at St. Thomas's, the late Mr. Rouquette, was initiated into Mr. Dunhill's technique, and performed a number of operations, and since his death the work had been carried on by Mr. Romanis, who had performed over 200 operations, with only five deaths—a remarkable result when it was remembered that these were not cases selected as specially favourable. At the time his article on exophthalmic goitre appeared in Allbutt and Rolleston's *System of Medicine* (1903) the mortality at operation was given as 20 per cent. The effects of the operation depended to a great extent upon the amount of gland which the surgeon was able to remove. Some cases had required more than one operation.

The first case of the series which started in 1915 required three operations: in the first the right lobe was removed; in the second, fifteen months later, the greater part of the left lobe was removed; and in the third, eleven months later still, two thirds of the remaining portion of the left lobe was removed. The result after the third operation was entirely satisfactory. The heart quietened down, and, although the eyes were still prominent, the frightened look had disappeared, and the patient had since won two first prizes for pianoforte playing, and showed no nervousness when playing in public.

The usual result following partial thyroidectomy was greater tranquillity, an increase of the general strength, and a slowing of the heart's action. Usually, when only one lobe was removed, amelioration was all that could be hoped for, though the prospects were much better than they would have been without an operation at all. The exophthalmos was the most persistent symptom.

With regard to contraindications (Dr. Mackenzie continued), auricular fibrillation might be thought to contraindicate operation, but he had seen cases operated on in which this had been present, and the result of such operation was that the heart became quieter and more regular. He had ventured an operation also in a case in which the patient was bordering on mental derangement, and her delusions disappeared. The presence of undoubted diabetes would certainly contraindicate, but he did not think that the occasional presence of sugar in the urine would militate against operation. Dread of the operation was perhaps the most important contraindication; he would be very unwilling to advise operation on any patient who dreaded it much. On the whole question his feeling was that every patient should have a fair trial of medical treatment, and if she did not

improve within a reasonable time—three or six months—the possible benefits of surgical treatment should be mentioned to her. In thirty of his private cases which had been operated on the average duration of symptoms before operation was four and a half years, so that no one could accuse him of rushing into operation. The results of medical treatment were disappointing in many cases, while, as for x-ray treatment, for a considerable number of years he saw no cases which he could regard as cured by x rays. At last one patient who had been coming to the x-ray department for three years appeared to be cured of the exophthalmic goitre, but developed myxoedema, which yielded to thyroid treatment, and this patient then showed as good a cure as he had seen in any case. No treatment was ideal; the ideal treatment would be the provision of some antidote to the thyroid poisoning.

Operation: Conditions and Technique.

Mr. JAMES BERRY said that although his own views regarding the value of operation had not changed substantially, he was rather less sanguine than before, owing to the great tendency to relapses even after operations most successfully performed. He congratulated Dr. Mackenzie on his "conversion." There was a time when both Dr. Mackenzie and himself were strongly opposed to all operations for exophthalmic goitre. His own "conversion" was of long standing, Dr. Mackenzie's was more recent, but the tardy convert often became the most zealous apostle. On the general question he had two remarks to make: (1) The result of operation was that within a very short time—generally a few days—the patient felt that she had derived immense benefit from the operation; the feeling of depression disappeared, and the tachycardia diminished very greatly and might disappear completely in a few weeks. (2) The operation, even when carried out under the best conditions, involved considerable danger to life—a danger far greater than in operations for simple goitre. The mortality in this latter condition had been reduced by most masters of thyroid surgery to a fraction of 1 per cent, but the operation for the removal of true exophthalmic goitre generally involved a mortality of at least 3 to 5 per cent. At the same time, too much stress must not be laid upon mortality. The disease was a very serious one, and a mortality even of 5 per cent. was a risk which most patients suffering severely from this disease would willingly undertake. In speaking of exophthalmic goitre they did not always mean the same thing. At least three different conditions were included in that term. In one of these, which he called false exophthalmic goitre, the patient had an ordinary simple goitre, with a little tremor, a little nervousness, and no exophthalmos. He would not dream of putting such cases into his statistics, though they were commonly called exophthalmic. The mortality here was not in the least above that of ordinary goitre. In another condition there was an adenoma—a tumour very likely of long duration—to which all the symptoms of exophthalmic goitre had been superadded. Thirdly, there was the true exophthalmic goitre with the well known symptoms.

In Mr. Berry's view, only two operations had any value—namely, the removal of a portion of thyroid gland and ligation of the thyroid arteries. The ligation of the inferior artery he had completely abandoned; it was a difficult operation, and of scarcely less danger than the removal of the whole lobe, which was far more likely to cure the disease. The ligation of the superior artery was comparatively easy, and, on the whole, safe. He had not lost a case for eight years, during which time he had performed a large number of these operations.

His hospital cases from 1913 to 1919 where ligation of the superior thyroid artery was done numbered 27 females and one male. The particulars were as follows:

Bilateral (simultaneous)	5 cases
Bilateral (at different times)	14 "
Unilateral	9 "

Nine of these 28 subsequently underwent extirpation of one lobe.

In the removal of the gland the question arose as to how much should be removed. He had almost abandoned the practice of removing both lobes; it involved too much risk. Nor did he usually remove the whole of one lobe. It was wrong to do thyroidectomy when the patient was suffering from acute excitement, yet it was just during the

riod of exacerbation that the patient, and sometimes the neral practitioner, were most anxious for operation. e surgeon should resist the temptation to operate at ch a time. Operation should never be performed until e patient had been resting quietly in hospital for at ast a few days. He did not operate at any stage on ntients who were steadily improving, nor on patients— d there were many such—who did not feel at all ill. e was coming more and more to believe that a very ght open ether anaesthesia was preferable for most cases. xcept where there was acute intoxication or myocardial egeneration it was usually haemorrhage that was the ause of death in operations for exophthalmic goitre. ven a comparatively small amount of haemorrhage, hich would be of little or no importance in goitre, might asily be fatal in exophthalmic goitre. The after-treat- nent might be summed up in the one word "water." The atient should be encouraged to drink many pints.

Mr. Berry gave the following statistics of his results after the removal of true exophthalmic goitre during the years 1913-19:

Patients practically well	53
Much improved	18
Improved	1
No improvement	2
Worse	1
Died after operation	3

The Justifiability of Surgical Risk.

Mr. T. P. DUNHILL dealt with the grounds on which, he considered, some intervention other than the purely medical might be necessary. Death, he said, was not the only tragedy in exophthalmic goitre. An eye might be lost; many cases also went on to a generalized oedema. Treatment other than medical, therefore, must at least be considered. All would admit that many cases recovered under medical treatment. When it was found out which cases recovered, and why they recovered, a great advance would be made. The idea of operation should not be entertained until after the removal of any toxic focus, complete rest, and systematic drug treatment. His personal experience of x-ray treatment had not been satisfactory. The pulse did not come down, the exophthalmos did not alter, and the tremors did not disappear. What was the outlook for patients who were not improving under medical treatment? Was it sufficient for medical men to claim that at least they had kept them alive? It was said that the disease ended either in recovery, myxoedema, or death. Some recovered certainly, very few went on to myxoedema: what about the others? Numbers of them were in various grades of ill health, down to being bedridden wrecks. It was justifiable to take some risk to free these patients from the miserable existence they led. As for the amount of relief which might be expected, the exophthalmos would generally disappear if the cases were sent for operation within a reasonable time, and if sufficient gland tissue was removed. In the strongly marked cases resistant to medical treatment, putting the word "cure" on one side, he would say that after operation these patients might be raised to the industrial level. A great many cases would not be cured without removal of a portion of the second lobe. He had never yet lost a patient after a second operation for exophthalmic goitre. In some cases the removal of one lobe might turn the scale, particularly cases which were nearly winning their own battle, but these were not usually the cases which came to the surgeon. It was very important to conserve the blood supply of the portion which was left intact. The thyroid operation in exophthalmic goitre differed from abdominal operations, which might be undertaken by the surgeon with some equanimity, and in which it was not a matter of great importance whether the time taken was twenty minutes or an hour and a half. The operation for exophthalmic goitre had never been done by him without fear and grave anxiety, even in cases which seemed simple. He pleaded for earlier operation, which would be safer and would relieve the strain on patient and surgeon alike.

The Natural History of the Disease.

Sir W. HALL-WHITE said that he had to admit that there was no specific medical treatment: the treatment was symptomatic. But he thought it might interest the Sections if he gave an account of the natural history of the disease. He had lately been trying to obtain particulars regarding all his hospital and private patients

during the last twenty years. A number were untraceable, but he got replies regarding 102, and he submitted his figures to an actuary to discover whether the expectation of life in people with exophthalmic goitre was much less than in normal individuals. The actuary replied that the figures were not sufficient data for a very definite opinion, but, roughly speaking, it appeared that the mortality among the sufferers from exophthalmic goitre was double that among healthy females of the same age. That gave rather an exaggerated view of the situation, because these people were young adults among whom, in health, the mortality was very slight, so that even double this mortality would not be a great mortality. It had to be remembered also that all these were cases of exophthalmic goitre which were bad enough either to go to hospital or to be sent by their doctor for a second opinion. He thought it might be concluded that the outlook for sufferers from exophthalmic goitre was that they were rather more liable to die than healthy people of the same age. This conclusion seemed justified by the fact that it was quite unusual to find the disease in the *post-mortem* room. The disease rarely killed, and, left to themselves, the people must generally get well, otherwise many people in old age would be found suffering from this condition, and such was not the case. Among the hospital cases which he had traced, 65 per cent. were found to have got quite well, 30 per cent. were much better, and 5 per cent. were better in some respect or other. Among the private cases the proportions were 74.5 per cent., 19.1 per cent., and 6.4 per cent. respectively. He had excluded from these figures the patients on whom operations had been done. There were cases in which he would willingly ask the surgeon to operate because they seemed to be going downhill, yet they might take a turn for the better without operation. He had notes of cases discharged from hospital as incurable many years ago in which, some time after discharge, a certain improvement began, and they were now quite well. He was not opposed to operation, but he thought that many cases would do quite well without it. All that they could do at present was to say to the sufferer, "We have been watching you for weeks or months (as the case might be); you are not getting any better, but at any time the natural history of your complaint seems to show that you may take a good turn. Nevertheless, we can offer you an operation with a mortality—diminishing as years go on—of, at present, from 3 to 5 per cent."

The Reason for Heart Failure.

Dr. J. S. GOODALL said that on beginning to study this condition he was soon impressed by the fact that, whether the case was looked at from the medical or the surgical standpoint, the heart was of supreme importance. A large number of the cases which were treated by physicians appeared to get gradual cardiac failure, while a certain number treated by surgeons died suddenly from the same cause. He commenced an investigation into the condition of the heart in this disease. He was particularly fortunate, because at the time he began this study he had at his disposal what he might term a clinical unit—an assembly in a nursing home of the most modern appliances for examining the heart: a four-stringed oscillograph, a two-stringed electro-cardiograph, an instantaneous x-ray apparatus, and a biochemical laboratory. Many hundreds of observations were made before the war came to upset some, though not all, of the arrangements. Ventricular fibrillation appeared to be the reason why these exophthalmic goitre cases succumbed to heart failure after operation, and the conclusion he arrived at from a study of his records was that there were two factors which tended to ventricular fibrillation, one of them a pre-existing myocardial degeneration and the other a high blood pressure. He believed that the blood pressure in exophthalmic goitre was triphasic: first a temporary rise, very transient, then a fall, and then a rise again. After operation the blood pressure tended to rise, and that rise might be so considerable that the blood pressure at the end of the operation was twice the pressure at the start. If there was a degenerated myocardium and it was suddenly confronted with a high blood pressure it was reasonable to expect calamity. If the myocardium was degenerated and the blood pressure high the surgical risk was very great.

PAROTID TUMOURS.

At a meeting of the Pathological Section of the Liverpool Medical Institution held on January 20th, with the President, Dr. J. E. GEMMELL, in the chair, after the various specimens were demonstrated and described, Mr. ROBERT KENNON read a paper on tumours of the parotid gland. The material upon which the paper was based consisted of 121 cases of parotid tumour operated upon at the Royal Infirmary, together with pathological reports and slides obtained from Professor E. E. Glynne and the private collections of Mr. Parker, Mr. Paul, and Mr. Thelwall Thomas. On analysis 91 cases were adenomata, 27 carcinomata, 6 sarcomata.

Of the adenomata, in 35 cases the after-histories had been obtained. Out of 32 cases 22 were alive and well, the average duration of each case being eleven years, while another case had died without recurrence seven years after operation; 5 had had recurrence. The tumour was most frequent in females; the average age at onset was 50 years, at operation 57 years—a delay of seven years before surgical aid was sought. Trauma had occurred in 4 out of 29 cases. Pathologically the tumour was considered to be adenoma with mucinous degeneration, and with later regeneration as cartilage. There was no evidence to support the branchial or endotheliomatous origin of the tumours. Recurrence was shown to be due to accumulation of the field of operation with fresh cells, which were found to be most active immediately beneath and frequently split the capsule. This was also considered to be the mode of growth during life. The recurrence was immediate in 5 out of 9 known time periods, and averaged one and a half years; and reoperation took place on the average after 5.5 years' delay. Three cases, previously the subjects of recurrence, had reached the five years' limit of cure. No evidence was obtained that operation hastened recurrence or shortened the life of a patient.

Carcinomata were of two types—the spheroidal and the cuboidal cells; 35 per cent. originated in simple tumours. More frequent in females, the malignant change in a simple tumour occurred about the age of 38. Pain, rapid growth, early fixation, and facial paralysis characterized these tumours. Lymphatic glands were involved late.

Sarcomata, round and spindle celled varieties, occurred; the only case traced died five years after the onset of the disease, and two years after operation. Radium had a beneficial effect on certain cases of simple origin.

The seventh ordinary meeting of the Liverpool Medical Institution was held on February 3rd, with the President, Dr. J. E. GEMMELL, in the chair. Mr. THURSTAN HOLLAND read a paper on "Some of the rarer conditions of bones." He showed radiographs of some of the accessory bones of the foot and of the sesamoid bones, and discussed their importance from the point of view of industrial injuries and compensation. Radiographs of six cases were shown in which the bone of Vesalius was present in both feet; and the question was discussed in detail of differentiating between the sesamoid of the peroneus, the presence of a true bone, and epiphyses at the base of the fifth metatarsal. Two cases of Köhler's disease of the scaphoid bone were demonstrated, and radiographs showed the condition at an initial stage and two years later. The paper concluded with a description of an exceedingly rare condition of the patella, in which radiographically there appeared to be an epiphysis on the upper and outer sides of both patellae.

Dr. BALME delivered an address on "Surgical practice in China and recent developments in medical education," and showed a large number of interesting lantern slides.

RADIUM THERAPY.

At a meeting of the Nottingham Medico-Chirurgical Society on January 5th Dr. STANLEY GREEN of Lincoln read a paper on radium therapy. After a description of the apparatus and the methods which he employed, Dr. Green said that his experience was that primary carcinoma could not be cured by radium, and that where operation was possible the surgical procedure should be carried out; if recurrence took place it could frequently be kept in check by radium, cases of carcinoma mammae being described where this took place. The treatment of carcinoma of the rectal ampulla with radium, after left inguinal colostomy, was also recommended and described, and Dr. Green put forward a plea for the treatment by radium of inoperable cases of carcinoma of the cervix uteri, pointing out that by this means possibly 20 per cent. of these cases would become operable. The favourable results of radium therapy in superficial conditions such as keloid cicatrix, lupus vulgaris, and lupus erythematosus,

was emphasized, and Dr. Green mentioned five cases of endothelioma of the nasal septum which had been successfully treated by radium. The treatment of rodent ulcer by radium was strongly recommended as a result of the numerous successful cases of varying dimensions that the speaker had had, while he had treated two cases of cavernous naevi of the face with excellent results.

A CLINICAL meeting of the West London Medico-Chirurgical Society was held at the West London Hospital on February 4th, with the President, Dr. F. J. MCCANN, in the chair. A number of interesting cases were shown by Mr. ASLETT BALDWIN, Mr. B. SANGSTER-SIMMONDS, Dr. BURNFORD, Mr. TYRRELL GRAY, and others. Dr. S. D. CLIPPINGDALE exhibited a walking-stick, now in the possession of the Fagge family, said to be 200 years old, which was of the type used by medical men of the period, containing a phial and measuring glass in its hollow handle and shaft.

Reviews.

THE CEREBRO-SPINAL FLUID.

IN his monograph on the cerebro-spinal fluid Professor WILLIAM BOYD of Manitoba presents a useful and concise summary of the available knowledge with regard to the physiology and pathology of this important secretion. The origin, course, and destination of the cerebro-spinal fluid are considered in the light of the important experimental work of Leonard Hill, Weed, Dandy, and others. It would seem that the choroid plexus, although the chief, is not the sole source of the fluid; that the quantity in an adult man is probably in the neighbourhood of 120 c.cm.; and that experimental observations on the absorption of dye from the subarachnoid space, and its subsequent excretion into the urine, indicate that the fluid can be replaced four or five times over in the twenty-four hours.

Factors that are known to influence the flow are next considered, and attention is drawn to the interesting observation of Dixon and Halliburton that certain substances, such as extracts of brain or choroid plexus, act as cerebral "lymphagogues," probably through the action of a special hormone. Even more important, however, is their observation that excess of carbon dioxide in the blood causes an increase in the flow of the cerebro-spinal fluid. This is the probable explanation of a fact observed during the late outbreak of cerebro-spinal fever, namely, that far more cerebro-spinal fluid may be obtained when lumbar puncture is performed under a general anaesthetic than is the case without one. Possibly, as Professor Boyd suggests, the increased flow under such conditions is brought about by the circumstance that the cerebro-spinal fluid is a means whereby carbon dioxide is rapidly excreted from the blood; hence, when under the anaesthetic the blood content of carbon dioxide rises, the flow of cerebro-spinal fluid is stimulated.

It would appear that comparatively few substances pass from the blood into the cerebro-spinal fluid. This impermeability of the choroid, however, is not quite complete. According to Professor Boyd, alcohol, chloroform, and acetone are allowed ready passage. Whether urotropin can pass through is disputed. On the contrary, substances injected into the cerebro-spinal system are rapidly absorbed into the blood, and may appear in the urine within twenty minutes. Even more striking than this rapidity of absorption from the cerebro-spinal fluid is the amount of fluid that can be absorbed by that route. Professor Boyd directs the attention of therapists to the fact that "anything up to a litre of normal saline may be run into the subcerebellar cisterna of a dog, and absorbed in the space of one or two hours." The greater part of this absorption appears to take place from the cranial subarachnoid space.

The changes undergone by the cerebro-spinal fluid in disease are thoroughly dealt with, and we note with approval that the author makes full reference to the work of British observers in this field. Amongst other things, attention is drawn to the valuable evidence to be obtained in cases of

suspected uraemia by measuring the urea content of a sample (5 c.cm.) of cerebro-spinal fluid, and also to the recent demonstration by Cauti of the value of this procedure for distinguishing certain cases of cardiac disorder clinically closely simulating uraemia from the true condition. It would seem to be established that measurement of the amount of urea in the cerebro-spinal fluid is not only of practical importance in the diagnosis of uraemia, but, further, that, as Mestresat first pointed out, the quantity of urea found there during an attack of uraemia is a good guide to prognosis.

We can cordially recommend this monograph, which satisfies a distinct want and provides an excellent synopsis of a subject of increasing importance. The subject matter is well set out, the book is clearly written, and its value is greatly enhanced by the fullness of the references. The only criticism that we have to make is that reference to work done in this country on the specific therapy of cerebro-spinal fever during the recent outbreak is lacking: a defect that doubtless will be remedied in future editions.

GOUT.

To write a comprehensive and intelligible account of gout is a difficult task, and, indeed, is probably harder now, on account of the greater accumulation of data without a corresponding justification for dogmatism, than at the time when the treatises of Sir Alfred Garrod (1859) and Sir Dyce Duckworth (1890) appeared; with them comparison must inevitably arise. In his pleasantly written volume on *Gout* Dr. LLEWELLYN JONES LLEWELLYN² has succeeded in providing the reader with a fair and well-proportioned account of the very varied views of other workers, past and present, and at the same time has made his convictions, derived from much experience at Bath, quite clear. The theoretical and the practical considerations are skillfully balanced, but the practising physician rather than the laboratory worker appears to be the directing spirit, as, indeed, should be the case.

After a review of the chemistry of gout, the weight of clinical evidence is shown to be against the primary renal origin of gout; and in the section on uricaemia full advantage is taken of the results from Folin and Denis's colorimetric method of detecting uric acid in the blood, and of McLester's figures showing the uricaemia of normal persons and in various diseases. Contrary to what might be expected, there is not any constant relation between uricaemia and uratosis or the presence of tophi: Dr. Llewellyn believes that formation of tophi is preceded by a local inflammatory reaction of varying severity, and that, as uric acid and its precursors are non-toxic, the tophi are the result and not the cause of the inflammation. He is a strong advocate of the infective theory of gout, and insists that inflammatory reaction invariably precedes all gouty processes, articular and ab-articular, the inflammation being due to infection or subinfection which may be of various kinds and is therefore not specific. Local foci of infection, such as oral sepsis and tonsillitis, are extremely common in the gouty, and thus cause the arthritis; further, the probable diminution of rheumatic fever since tonsillectomy has come into vogue is compared with the increasing rarity of gout which synchronizes with the more general treatment of oral sepsis. The gastro-intestinal disorders which chequer the course of gout increase the pathological activities of the intestinal flora and incidentally the liability to infection at various sites of the alimentary canal. The author holds that it is not the quality but the quantity of food that is responsible for gout, by producing a toxic condition of the blood plasma and so lowering the resistance of the individual to microbe invasion; alcohol and lead, which do not produce gout in the absence of an hereditary proclivity, similarly act by impairing the protective mechanisms of the body and so favouring infection, especially from the gastro-intestinal tract. Mr. W. M. Beaumont contributes a chapter on ocular disease in the gouty, and, after full discussion of the late Sir Jonathan Hutchinson's views on iritis, concludes that it is unwarrantable to speak of gouty ocular disease, for there is nothing in the character of the inflammation specific of gout.

In his full clinical account of the disease Dr. Llewellyn points out that gout disposes to fibrositis by favouring infection, that acute gout is not infrequently complicated by fibrositis, and that the same infection sets up these two changes. A very definite view is expressed about irregular and retrocedent gout; there is no anatomical evidence of gouty inflammation in the viscera, and the gastro-intestinal disorders, such as dyspepsia and acidity, attributed to gout, are in reality etiological factors and not symptomatic manifestations of that disease; the cases of so-called "retrocedent" gout to the heart or the brain are usually due to myocardial degeneration, arterio-sclerosis, or renal disease.

The section on the important subject of treatment bears witness both to the author's practical experience and to his sense of proportion. Commencing with the radical treatment of local foci of infection or toxic absorption, stress is laid on the importance of being on the look-out for more than one such focus; thus oral infection may be associated with tonsillar, aural, cholecystitic, or appendicitis infection. With regard to diet, it should be remembered that each gouty subject is a law unto himself and that it is the individual and not the uric acid that must be treated. The dietary should not be stereotyped, but should be directed to obviate dyspepsia and promote a sepsis of the alimentary tract. With regard to the relative claims of colchicum and atophan, the author points out that the vegetable drug influences the real cause of the arthritis, whereas the synthetic product promotes absorption and elimination of the resulting uratic deposits, and should therefore be given after a paroxysm in order to prevent tophaceous formations.

DISEASES OF THE LUNGS AND PLEURAE.

The nine years that have elapsed since the date of the last edition have necessitated many changes in the sixth edition of the well known work *On Diseases of the Lungs and Pleurae*: by Sir R. DOUGLAS POWELL and Sir P. HORTON-SMITH HARTLEY. New chapters have been added on chylothorax, massive collapse of the lung, sporotrichosis, and artificial pneumothorax; the section on haemothorax has been supplemented by an account of haemothorax following wounds of the chest, thus summarizing the British experience gained during the war. Reference is duly made to the four types of pneumococci established at the Rockefeller Institute, and to the value of the anti-pneumococcal Type I serum in cases proved to be due to this type. It would be interesting to know if this form of differential treatment has been attempted in this country, and if the authors have had any personal experience of it; they have, however, employed pneumococcal vaccines in many cases of pneumonia without any well-marked beneficial effect, and sensitized (preferably autogenous) vaccines with perhaps more encouraging results. The rather condensed account of bronchopneumonia contains a reference to mustard-gas poisoning. The description of influenza pneumonia might perhaps have contained some reference to W. G. MacCallum's splendid monograph on the pathology of the pneumonia in the United States Army Corps during the winter of 1917-18. The anaphylactic origin of asthma and the recent work of Drs. John Freeman and Chandler Walker find a place, and a wise caveat is entered as to the use of therapeutic serums in asthmatic subjects.

The description of pulmonary tuberculosis occupies two-fifths of the volume, and reflects the mature and wide experience of the authors; many additions, such as Professor Karl Pearson's and Dr. John Brownlee's work on epidemiology, have been made, and new observations and views are submitted to careful criticism. Hilum tuberculosis is regarded as an unnecessary addition to nomenclature, as in the adult there is reason to doubt the correctness of the statement that tuberculosis spreads continuously outwards from foci at the hilum; tuberculosis of the glands in the hilum is of course well recognized, but this is not the form of disease to which the term is usually applied. The remarks on tuberculin have been considerably curtailed in accordance with the opinion that, except in special cases, less value than formerly can

¹ *Gout*, by Dr. Llewellyn Jones Llewellyn. London: William B. Eerdmans, 1918. 1 plate.

be attached to its use; or? . . . of the dosage, the cubic millimetre, as . . . Morland and Riviere, is employed, inst. . . . centimetre. In conclusion, this familiar work, which is only some fifty pages longer than the last edition, can confidently be recommended as a safe guide to the practitioner in search of authoritative medical opinion in this country at the present time.

MACEDONIA.

PROBABLY it is true to say that, as the authors of *Macedonia: A Plea for the Primitive* would imply, less is generally known of Macedonia, its peoples and their customs, than those of any other part of Europe. This is true in spite of the fact that a British force was in occupation of the southern parts for three years, and that over 400,000 men passed through that force. For the majority, however, the opportunities of observation were very limited; the authors of this book were more fortunate, and appear to have visited nearly all parts of the country, among others Mount Athos and some of its monasteries, which can have changed but little since Curzon wrote his great book. The volume is not arranged after the manner of a guide-book, but according to subjects; thus there are chapters on native dress, on villages and houses, on the products, among which tobacco and dried fruit (currants) are probably the most important; on the Greek Church and the Turkish mosque, and on marriage customs. Agriculture is in a primitive stage. Threshing is carried on by a method which we have not hitherto seen described: corn is laid out on the threshing floor "to a depth of an inch or more, and large pieces of wood, like flat toboggans, . . . underneath with sharp projecting flints, are dragged over it by donkeys, ponies, or oxen." The flints, it is stated, are chipped after the prehistoric manner; this is very probable, for the last of the East Anglian flint-chippings died only a few years ago. Three chapters are given to Salonica, the last describing the great fire which destroyed the larger part of the city in August, 1917. The pleasure of reading the book is greatly increased by Dr. H. A. Fawcett's drawings, four in colour, and many in black and white. The text, we gather, is by Mr. A. Goff, whose style is rather unusual. "Simplicity is Nature's first step and the last of Art" is taken as a motto, and there are many references to it, but the author does not seem to have taken it to heart. Again, such a phrase as "a full conception of the degree of prolixity which it [insect life] attains" seems to need reconsideration.

NASAL ANATOMY.

Dr. SCHAEFER, in his monograph on *The Nose, Paranasal Sinuses, Nasolacrimal Passage-ways and Olfactory Organ in Man*,⁴ has presented an elaborate survey of the anatomy of these parts in the widest sense of the word. The author has been impressed with the unfortunate results of teaching students of anatomy one rigid description as the typical form of each region, organ, and structure in the body. Some general instruction of this nature is clearly necessary to form an elementary understanding of anatomical structure, but the author very wisely emphasizes the fact that a series of dissections soon shows that there is no fixed and unalterable type in many parts of the human body. Students, however, are very apt to acquire the idea that any deviation from an arbitrary standard constitutes an anomaly, whereas it would be almost impossible to find a body that answers in every detail to the typical form, which is a kind of average taken from a large number of specimens. In the nose wide departures from the composite anatomical standard are particularly frequent. The present volume is of value, both in establishing this general idea and also in describing the large number of structural variations which occur, and in tracing the developmental origin of their production. An excellent example of this is furnished by the variations in the nasolacrimal ostium, which the student usually conceives as an

opening guarded by the valve of Hasner. The clinical value of such anatomical knowledge, especially when based on a sound general conception, cannot be over-estimated. The chapters which concern the accessory sinuses, and especially the section dealing with the frontal sinus, are very good and of great practical value.

The work is founded on the author's observations and researches; he is sparing in his references to other publications, and has not attempted a general survey of the literature of the subject; nevertheless the book is sufficiently comprehensive. Some rather doubtful matter on the physiological relations of the nose to other parts has been introduced, presumably for the sake of completeness. The book, however, is one which well repays close study, and for anyone interested in the numerous anatomical problems connected with the nose and its accessory sinuses the illustrations are in themselves an education.

THE TRIAL OF THE WAINWRIGHTS.

THE "Notable English Trials" series appeals in a double sense to medical men, first to their professional interest in medico-legal problems and then in respect of human nature and its manifold twists and unexpected features. A good detective story usually has a peculiar attraction to a mind trained to track out the origin and course of morbid function, and this series shows how greatly fact may exceed fiction in its surprises and fascination. The twenty-fourth volume of this series, *The Trial of the Wainwrights*, edited by the late H. B. Irving,⁵ who also brought out the volumes on Franz Müller and Mrs. Maybrick, is an admirable case in point. In the introduction the editor has graphically sketched the murder of his paramour Harriet Lane by Henry Wainwright, the brushmaker of the Whitechapel Road, in 1874, his successful concealment of her remains for a year, their dramatic discovery when he moved them to what would have been a safer hiding place, his trial in company with his brother Thomas, and his execution. As some will remember, the body was originally buried with chloride of lime, which preserves rather than destroys human remains, and so led to the murderer's undoing when, a year later, the boy to whom Wainwright entrusted the grim parcel, found to his horror a human hand, and straightway communicated with the police.

Wainwright was not the first nor the last man to commit murder in order to preserve a respectable reputation, and an interesting comparison is drawn between him and John Tawell the quaker, John Beale, and Cadwallader Jones, like him married men who murdered their mistresses, and his namesake "kind light-hearted" Thomas Griffith Wainwright, the friend of Charles Lamb. The full evidence of the later trial is illustrated by photographs of Henry Wainwright and some of the eminent counsel concerned. The very natural interest felt in the talented editor has been happily satisfied by an admirable appreciation from his friend Sir Edward Marshall Hall, who gives much interesting information about his criminological methods, and says: "If it had not been his fortune to be the son of a great actor and a great actor himself he might have earned fame as a great advocate, but his was the better rôle."

NOTES ON BOOKS.

SIR D'ARCY POWER has published his second Vicary Lecture on *The Education of a Surgeon under Thomas Vicary*,⁶ with many interesting illustrations. The lecture shows how much the education of a surgeon owes to the wisdom of a few great men in the critical times with which it deals, when the fraternity of surgery could no longer continue along the traditional lines and there was a real danger of surgery passing into the hands of a trade guild. An abstract of the lecture was given in our issue of November 13th, 1920.

We are indebted to the Registrar of the General Medical Council for a copy of the new edition of the *Report as to the Conditions under which Medical and Dental Practitioners Registered or Legally Qualified in Their Own Country may*

CURRENT NOTES.

Memorandum on Insurance Medical Records.

A MEMORANDUM on Medical Records (Document M. 29) divided into three parts—the first historical, the second instructional, and the third ethical—has been issued by the Insurance Acts Committee to all Panel and Local Medical Committees. It has been considered advisable to issue to every insurance practitioner the second and third parts of this Memorandum in order, on the one hand, that the duties of insurance practitioners in connexion with the keeping of record cards may be fully understood, and on the other that the true position with regard to the preservation of professional secrecy under the new system may be made clear to all concerned. The first part of the Memorandum, tracing the history of record cards from the inception of the Insurance Acts to the present date, may, however, be obtained by any practitioner on application to the Medical Secretary, 429, Strand, W.C.2.

Dangerous Drugs Regulations.

Last week's SUPPLEMENT contained the full text of the Memorandum on the draft Regulations under Section 7 of the Dangerous Drugs Act, 1920, which was forwarded on February 3rd, 1921, by the British Medical Association to the Home Secretary. The Regulations are for the control of all dealings in morphine, cocaine, ecgonine, diamorphine (heroin), and their respective salts, as well as in medicinal opium and any preparations containing not less than 0.2 per cent. of morphine, or 0.1 per cent. of cocaine, ecgonine, or diamorphine. It was recorded in last week's JOURNAL, p. 241, that the Permanent Under-Secretary of State in the Home Office, Sir Edward Troup, in a statement in the public press, had said among other things that a doctor will not have to enter the fact in a book whenever he gives a hypodermic injection of morphine or otherwise administers any of these drugs. Sir Edward Troup has since replied to the British Medical Association in a letter dated February 12th, written on behalf of the Home Secretary. The Secretary of State, he says, has very

carefully considered the representations submitted on behalf of the British Medical Association, and he thinks that it should be possible to meet most, if not all, of the points taken in the Association's memorandum. The Home Secretary suggests that in the first instance the Medical Secretary of the Association should discuss the various points with the representatives of the Home Office, and if after such discussion a deputation from the Association appears to be desirable, the Secretary of State will be very willing to receive one. On February 14th Dr. Alfred Cox, the Medical Secretary, had a conversation with Sir Malcolm Delevingne, an Assistant Secretary in the Home Office, who agreed to send his proposals in time for consideration by the Council of the Association at its meeting on February 16th.

Unemployment Insurance Act.

Two further decisions have been received from the Ministry of Labour in connexion with doctors' servants and the Unemployment Insurance Act (see SUPPLEMENT, January 22nd, 1921, p. 21). It should be borne in mind that exemption from the scope of the Act as regards domestic servants is governed by the following statement: "employed in domestic service except when the employed person is employed in any trade or business carried on for the purpose of gain." The Ministry's decisions are as follows: Contributions are payable in respect of a medicine boy and messenger and a coachman employed by a doctor. A covering letter states that these decisions will apply to persons employed in the same occupation under similar conditions, and that the decision regarding a doctor's coachman will apply in principle to chauffeurs employed by medical practitioners to drive them on their rounds to visit patients.

Handbook of the Association.

The question of the *Handbook* of the Association for 1921-22 will be under consideration by the Propaganda Subcommittee on or about March 16th. The Subcommittee would be grateful for any suggestions on the subject from Honorary Secretaries or other members interested. Copies of the current *Handbook* will, so far as possible, be sent to members who apply for them.

Scottish Committee.

The following, among other matters, were dealt with at a meeting of the Scottish Committee held on February 10th, 1921:

Report of Scottish Consultative Council.—It was decided to hold a meeting of Scottish representatives in May to consider the Report. A questionnaire is to be issued to Divisions on the recommendations contained in the Report; replies to be sent in before April 15th.

Scale of Fees to Practitioners under the Midwives (Scotland) Act.—No reply having been yet received from the Board of Health to the proposals put forward by the Committee, it was resolved to advise practitioners not to undertake to respond to the call of midwives until a satisfactory reply has been given by the Board.

Mileage Grant to Insurance Practitioners.—The Rural Practitioners Subcommittee reported that the grant for 1920 has now been distributed on the basis of the scheme agreed to by the Subcommittee. The total sum is £55,000, with an additional sum of £10,000 for areas of special difficulty. The object of the "grading" of the units in the scheme is to secure that quasi-rural practitioners shall not benefit unduly at the expense of the strictly rural practitioner, and that object seems to the Subcommittee to have been attained. Panel Committees, however, are requested to examine carefully the local distribution with this in view. It was noted by the Committee that the value of the "unit" is 1s. 8d. in Scotland, which is apparently less than in England, and the Subcommittee was requested to consider the matter.

Highlands and Islands Subcommittee.—The Subcommittee recorded its satisfaction that the Board of Health had agreed to their representations for an increase in the guaranteed minimum income in single-practice areas, and for an increase in the scale of fees chargeable to patients under the Board's scheme. It was resolved that the Board be urged to fulfil their promise to review the Highlands grant in the light of the alterations in the Lowlands mileage grant, and to base the case for increase on: (a) The fact of the specially arduous conditions in the Highlands, which are comparable, not with average Lowland rural areas, but with the areas of special difficulty to which the additional grant of £10,000 is applicable; (b) the fact that the Lowlands grant has been increased two and a half times; (c) the fact that the cost of motor travelling is still increasing.

The Report of the Distribution Committee.

The importance of this matter justifies a further allusion to this report, which was dealt with in the SUPPLEMENT of February 5th, p. 32. The concluding paragraph on the difficulties of obtaining returns of mileage refers to a subject on which the Insurance Acts Committee has made repeated appeals to those concerned. If those insurance practitioners for whom the mileage fund is provided and who are directly concerned in getting their proper share of this fund neglect to send in their returns, they must not be surprised if the result of the distribution is unsatisfactory to them.

To deal with another aspect of the work of the Distribution Committee, some public acknowledgement is due to the Chairman, Sir Woodburn Kirby, for his services to insurance practitioners. The medical members of the Committee and the departmental members are of course interested, each in different ways, in the money to be distributed. But the chairman has no interest beyond that of performing a public service, and Sir Woodburn Kirby, a busy and eminent accountant, has performed a real service to the medical profession in accepting a position which entails no small demand on his time and skill. He is connected by birth and by marriage with our profession, and it is pleasant to suppose that this may have had something to do with his willingness to accept and continue in the chair of the Committee.

Lending Library.

The Librarian will be glad to assist members of the Association in the selection of works to be sent them by post, in accordance with the arrangements for borrowing books that are notified each week on the last page of the SUPPLEMENT.

THE MEANS OF OBTAINING THE COLLECTIVE OPINION OF THE MEDICAL PROFESSION ON QUESTIONS OF POLICY.

THE Minister of Health made a request to a deputation from the British Medical Association on November 1st, 1920, that he should be provided with a body really representative of the whole profession, which he could consult on questions of policy, instead of being approached by half a dozen bodies each claiming to represent the profession. The matter has since then received the active attention of the Council, and certain sectional medical organizations have been invited to co-operate with the Association in forming such a body.

The Federation of Medical and Allied Societies called a conference on February 1st, 1921, with a view to discussing co-operation on the lines suggested by the Minister of Health. It issued a statement in which it laid down its ideas of the qualifications of such a body. The British Medical Association, amongst other bodies, was invited to the conference, but declined because it was itself engaged, at the suggestion of the Minister of Health, in trying to constitute a central medical committee representative of the profession as a whole.

The following memorandum, stating the views of the Association on the qualifications of a body professing to represent the medical profession as a whole, has been sent to the Federation, to the bodies whose representatives signed the invitation to the February 1st conference, to those other bodies invited to the conference, and to the Minister of Health:

MEMORANDUM OF THE BRITISH MEDICAL ASSOCIATION.

1. The Minister of Health, addressing a deputation from the British Medical Association on November 1st, 1920, complained of the number of bodies that approached him claiming to be representative of the profession, and asked that some one body recognised as representing the whole profession should be provided, so that he could consult it on matters of policy affecting the medical profession. Further, in a letter to the Chairman of Council of the Association, dated November 26th, 1920, the Minister said he was "satisfied that it would be impossible to secure the constitution of a representative body without the good offices of the B.M.A. in bringing them together," and went on to suggest that the Council of the Association "should now initiate action to secure the appointment of a body whose credentials will be incontestable."

2. The Association has accepted the Minister's suggestion, and has invited certain medical bodies to co-operate with it in constituting a body which will satisfy his requirements. The Association desires to state its views as to the qualifications of such a body.

Qualifications of a Body Representing the Medical Profession as a Whole.

3. In the first place the body must represent the views of the medical profession and the medical profession alone. The Minister has asked for such a body. When he wishes for the views of the Dental, Pharmaceutical or Nursing professions, he will naturally call on the organisations which represent those professions. They would not desire to have their views confused with those of the medical profession, and the medical profession would certainly not consider that representations from any body which attempted to fuse the interests and views of widely differing bodies ought to be taken by the Minister as the considered policy of the medical profession.

4. The body must be an immediately and directly responsible body—that is to say it must recognise the authority of its constituents and no other authority. It must be under the constitutional control of the whole of its constituents and without undue bias toward any one section of them. A body which the bulk of the profession felt they had no direct means of controlling would be worse than useless for the purpose of the Minister, and might do great damage to the interests of the profession itself.

5. The body must therefore be really representative. That is to say it must have modern constitutional methods of ascertaining the opinion of its constituents

and of securing their acceptance of agreements made on their behalf. The body as a whole, or the constituent parts of the body, must therefore have machinery, both central and local, for the purpose of eliciting opinions on policy.

6. The constituents of the body must be directly and intimately concerned in what is generally known as "medical politics," and they must be trained in expressing opinions on such matters. Bodies exclusively or mainly scientific have no concern with medical politics and have not the machinery for dealing with such matters.

7. The body must not profess to promote the interests of the community rather than those of doctors. Such a body would not be recognised by doctors as the body which primarily represents them and their views. Doctors are citizens as well as doctors, but what the Minister is understood to require is a body which will tell him what doctors and doctors think, whether as to the interests of their own profession or as to general questions of public health.

How far does the British Medical Association meet these Requirements?

8. The British Medical Association acting alone would be justified in claiming that it possesses the qualifications enumerated above. It contains 52 per cent. of the whole profession on the Register, and this percentage applies approximately to every section of the profession. If those who are not practising their profession, and what may be called the "floating medical population" be eliminated, the Association could be shown to include about 60 per cent. of the active members of the profession.

9. It is really representative of its members and has well-tried machinery, both local and central for ascertaining their views. The control of its members over the Association is thoroughly democratic and complete. Its members are trained, both locally and centrally, in dealing with medical politics. It does not profess to represent the views of other professions, but it does claim to know with greater certainty than any other body the opinions of the majority of the medical profession.

10. Moreover, the Association is recognised informally by large numbers of practitioners who do not belong to it as the body which voices the wishes and sentiments of the profession as a whole. It is very frequently consulted by non-members individually in their troubles; also by bodies of non-members, or bodies of local practitioners, some members some not. It is recognised by the public as the body which bears the same relation to doctors generally as, for example, the National Union of Teachers does to elementary teachers, or the Miners' Federation to miners. The Government has frequently made use of it as the body which can more adequately than any other body represent the general profession. To name only the most recent and most conspicuous example—the machinery of the Association, both central and local, was used by the Government for the purpose of providing doctors for the Services with due regard to the interests of the civil population. The Government recognised that there was no other existing body which had the machinery, and there was no question about the Association's ability to deal with and represent the views of practitioners, whether members of the Association or not.

11. The Association does not profess to include every member of the medical profession, and it knows of no organisation of any other calling which can make such a claim. The Association does claim to be by far the largest body of organised medical practitioners with a machinery capable of eliciting, by recognised constitutional methods, the views of the organised profession.

Co-operation of the British Medical Association with other Organized Medical Bodies.

12. In order to make itself as useful as possible to all sections of the profession the Association has always tried to work with organised bodies representing distinct sections of the profession. Representatives of the Society of Medical Officers of Health, the Medical Women's Federation, the Poor Law Medical Officers' Association of England and Wales, the Medico-Psychological Association, the Association of Certifying Factory Surgeons, and other bodies have frequently sat on Committees of the Association. All these Societies have on occasion attended on deputations to Ministers arranged by the Association. Most of them regularly and closely co-operate with the Association in its work for the pro-

fession. The three first-named societies have standing representation on some of the most important Committees of the Association.

13. The Insurance Acts Committee of the Association in a very special way represents the interests of the (approximately) 14,000 practitioners engaged in National Health Insurance work. A majority of the Committee consists of members elected directly by the Local Medical and Panel Committees of the country with no restriction as to whether their nominees are members of the Association or not. The Committee is directly authorised by a representative Conference, acting on behalf of the Local Medical and Panel Committees, to carry out all negotiations with the Ministry of Health on matters affecting practitioners engaged in National Health Insurance work.

14. Though the constitution of the Association and its traditional and regular co-operation with bodies representing special sections of the profession would justify it in claiming the qualifications required by a body representing the profession generally, it has invited these other bodies as independent organisations to join with it in attempting to form the body suggested by the Minister of Health.

15. The Association therefore feels that in accepting Dr. Addison's suggestion, if, as it expects, it secures the co-operation of the medical societies above named, it will be able to offer the Minister a body which (with the exception next to be mentioned) is really representative of all the organised medical profession, both generally and sectionally. The body when formed would, of course, consult with other medical bodies not directly represented on it when such consultation was thought desirable or necessary.

16. The exception referred to is that of the Royal College of Physicians of London and the Royal College of Surgeons of England. The Association recognises that the Councils of these bodies are able to speak for the consultant section of the profession in a way which is not open even to the British Medical Association which includes a large number of the Fellows of the Colleges. The Association has intimated to the Royal Colleges that their co-operation in the matter now under consideration would be greatly valued and that after the adhesion of the other bodies referred to has been obtained the Royal Colleges will be approached again more formally.

Meetings of Branches and Divisions.

ULSTER BRANCH.

Dangerous Drugs Regulations.

The Ulster Branch has passed the following resolution:

That the Ulster Branch of the British Medical Association, at its meeting in Belfast on February 10th, 1921, protests strongly against the action of the Home Secretary in having issued Regulations under the Dangerous Drugs Act imposing severe and impracticable restrictions on doctors in connexion with such drugs as cocaine, ecgonine, heroin, and medicinal opium, without any consultation with the British Medical Association.

That while anxious to help to suppress the use of habit-forming drugs the profession is against action which is not based on a knowledge of the customs of the profession as ascertained by consultation with its organization.

That a copy of this resolution be sent to the Home Secretary, the Chief Secretary, and to each of the members of Parliament for the Ulster constituencies.

METROPOLITAN COUNTIES BRANCH: CAMBERWELL DIVISION.

At a meeting of the Executive Committee of the Camberwell Division the Dangerous Drugs Act was considered, and it was resolved:

That, having fully discussed the draft Regulations as applied to medical men, we have decided that they are so impracticable that we must decline to carry them out.

A copy of the resolution was directed to be sent to the Home Secretary, the members of Parliament for the Division, the British Medical Association, and the medical press.

METROPOLITAN COUNTIES BRANCH: LEWISHAM DIVISION.

A MEETING of the Lewisham Division was held on February 4th, when the organization and ethical rules were adopted. The following officers were elected:

Chairman: Dr. G. W. Charsley. Vice-Chairman: Dr. Thomas E. White. Representative on Branch Council: Dr. James Gilchrist. Honorary Secretary: Dr. C. J. B. Buchan.

The Honorary Secretary reported that he had written to the Home Secretary about the draft Regulations under the Dangerous Drugs Act; it was decided that each member present should write also.

NORTH OF ENGLAND BRANCH: CLEVELAND DIVISION.

A BUSINESS meeting was held in the Zetland Hotel, Saltburn, on January 27th, when Dr. W. A. STEPHEN (Loftus) occupied the chair. The financial statement for 1920 was approved. It was resolved that the minimum fees to be charged to police authorities by members of the Division for professional attendance at the request of the police be half a guinea between the hours of 8 a.m. and 8 p.m., and one guinea between 8 p.m. and 8 a.m., and that such request be in writing. The Secretary was instructed to convey the resolution to the local authorities concerned. It was agreed to continue for 1921 the half-crown voluntary subscription for payment of Division expenses not defrayed by the local office.

The annual dinner was held in the Zetland Hotel, Saltburn, on February 3rd, when fifty-six members and friends were present, under the presidency of Dr. W. A. STEPHEN. A most enjoyable and successful evening was spent. Dr. T. M. BONY proposed the toast of "The Industries of Cleveland," which was suitably replied to by Sir ALFRED HUTCHINSON. The toast of "The Cleveland Division of the British Medical Association" was given by Mr. W. EDWARDS, M.A., in a humorous speech. The CHAIRMAN, in his reply, said that the Division was full of life as it embraced in its ranks all the specialists in the area, as well as the vast majority of the general practitioners. He was particularly glad to see the close intercourse between the members of the country and Middlesbrough sections. "Sister Practitioners" was proposed by Dr. J. A. LONGLEY and responded to by Rev. H. HUMPHREY, D.S.O., and by Mr. GEORGE BARKLEY, Minister. "The Guests," proposed by Dr. A. REYNOLDS, was replied to by Mr. C. S. SCH. Deputy Mayor of Middlesbrough, and Mr. T. W. RILEY.

SOUTH OF ENGLAND BRANCH: SUNDERLAND DIVISION.

The annual meeting of the Sunderland Division was held on February 1st, when Dr. R. G. BELL was in the chair. The annual report and financial statement was presented.

The following officers were elected for the coming year:

Chairman: Dr. R. G. BELL. Vice-Chairman: Dr. CHALMERS. Honorary Secretary and Treasurer: Dr. H. ROYD CUNNINGHAM.

UGANDA BRANCH.

A MEETING of the Uganda Branch was held at Entebbe on November 24th, 1920, when the President, Dr. A. R. COOK, was in the chair.

A unanimous vote of thanks was accorded to Dr. J. H. REID for his services as honorary secretary of the Branch, on his resignation of the office, and his appointment as Representative in the Representative Body for 1921-22 was confirmed.

In view of the Colonial Office reference to private practice in the terms of appointment the whole question was discussed, and it was unanimously resolved:

That the Colonial Office be asked to inform all applicants for medical appointments in Uganda that at present in most stations in the Protectorate the income from private practice was practically nil.

It was unanimously agreed that the Secretary of State's ruling, that one-half of the M.O.H. allowance should be granted to medical officers and senior medical officers who enjoy the privilege of private practice, should be maintained.

It was resolved to resume the discussion on blackwater fever at the forthcoming general meetings, and the P.M.O. promised to open a discussion on blackwater fever at the meeting in January.

The scheme of temporary medical officers' appointments was discussed. It was decided to forward recommendations to the Colonial Office through the Governor, and also to express regret that the medical staff of the Protectorate was not larger than it was in January last, and to suggest that the immediate introduction of the West Coast scheme of pay and allowances, present and prospective, was absolutely essential for the welfare of the Protectorate.

The P.M.O. reported that the Governor had agreed with the opinion that medical women and Sinhalese doctors were both unsuitable for filling vacancies on the staff on account of the conditions of the country.

Association Notices.

MOTIONS FOR ANNUAL REPRESENTATIVE MEETING, NEWCASTLE, JULY, 1921.

NOTICES OF MOTION by Divisions, Constituencies, or Branches, for the consideration of the Annual Representative Meeting of the Association, commencing Friday, July 15th, 1921, proposing to make any addition to, or any amendment, alteration, or repeal of, any Article or By-law, or to make any new Article or By-law, or proposing material alteration of the policy of the Association in matters relating to the honour and interests of the profession or of the Association, must be published in the

BRITISH MEDICAL JOURNAL SUPPLEMENT not later than May 14th, and for this purpose should be received by the Medical Secretary not later than April 30th.

ELECTION OF MEMBERS OF COUNCIL FOR 1921-22 BY BRANCHES OUTSIDE THE UNITED KINGDOM.

The following being the only nominations received for election to the Council for 1921-22 by Branches outside the United Kingdom (February 12th was the last day for receipt of nominations) are elected Members of Council for the periods stated:

No Nomination. South Australian, Tasmanian, Victorian, and Western Australian Branches.

Dr. H. A. FRANCIS (for two years 1921-23). New South Wales and Queensland Branches.

Dr. DAVID EWART (elected in 1920-21 for three years). New Zealand Branch.

No Nomination. Barbados, Bermuda, British Guiana, Grenada, Halifax (Nova Scotia), Jamaica, Leeward Islands, Montreal, St. John (New Brunswick), Saskatchewan, Toronto, Trinidad and Tobago Branches.

Lieut.-Colonel R. H. ELLIOT, I.M.S. (ret.). Assam, Baluchistan, Bombay, Burma, Ceylon, Hyderabad and Central Provinces, Punjab, South Indian and Madras Branches.

No Nomination. Hong Kong and China, Malaya Branches.

Dr. T. D. GREENLEES. Border (South Africa), Cape of Good Hope (Eastern), Cape of Good Hope (Western), East Africa, Egyptian, Gibraltar, Grigoland West, Malta, Natal Coastal, Natal Inland, Nyasaland, Orange Free State and Basutoland, Pretoria, Rhodesia, Uganda, Witwatersrand Branches.

* Lieut.-Colonel Ward, C.B.E., D.S.O., was also nominated for this group, but has stated that he will be unable to give the time necessary, and so will not seek election.

BRANCH AND DIVISION MEETINGS TO BE HELD.

EDINBURGH BRANCH.—The winter clinical meeting of the Edinburgh Branch will be held in the Royal Infirmary on Friday, March 4th. All members of the profession are cordially invited. The museum will be open from 11 a.m. Arrangements will be made for holding special clinics during the forenoon. The clinical meeting will be held at 3.15 p.m. Those who have patients, specimens, etc., to show are requested to communicate with Dr. John Eason, 35, Melville Street, or Mr. J. W. Struthers, 15, Ainslie Place, not later than February 20th. At 5 p.m. Dr. J. S. Haldane, LL.D., F.R.S., Oxford, will deliver a lecture on "Some recent advances in the physiology of respiration, circulation, and renal excretion." There will be dinner at 6.30 p.m. in the Caledonian Station Hotel; morning dress; dinner ticket, price 10s. 6d. Members of the Branch are requested to notify the Honorary Secretaries not later than February 28th whether or not they intend to be present.

METROPOLITAN COUNTIES BRANCH: CAMBERWELL DIVISION.—A meeting of the Camberwell Division will be held on Wednesday, March 2nd, when Dr. H. C. Cameron, of Guy's Hospital, will give an address on Children.

WORCESTERSHIRE AND HEREFORDSHIRE BRANCH.—The spring meeting of this Branch will be held at Ledbury on Thursday, April 14th, when a British Medical Association Lecture will be given by Mr. P. L. Daniel, F.R.C.S., on "The differential diagnosis of acute abdominal conditions."

INSURANCE.

CORRESPONDENCE.

The New System of Medical Records.

SIR,—The letter from Sir William Hodgson on this subject, traversing the Memorandum issued by the Insurance Acts Committee, and condemning at some length and somewhat illogically, if I may say so, the whole system, demands a reply.

The Conference of Local Medical and Panel Committees held last October instructed its executive body—the Insurance Acts Committee—of which Sir William is a member, to hold its hand, neither condemning nor approving until sufficient time had elapsed to allow a considered judgement to be given, and a month seems hardly long enough for that purpose.

The first part of the Memorandum makes it quite clear that the keeping of records was part of the bargain made with the Government in 1912, and was and has been paid for as such ever since. That the obligations, but not the payment, was suspended for four years during great national stress does not affect the fact, but rather the reverse.

Granted that a record must be kept—and this was accepted by the conference—the only question that can arise is as to the form which it should take. It had to be "simple and not involving a multiplicity of forms." The great objection to the old form of record was that any

value to the practitioner or his patient was lost by its having to be surrendered at the end of each year, whereby the whole of his more or less valuable clinical notes was lost, and he had to begin all over again entering names and addresses, etc.

The new record card certainly has several advantages—it is a continuous record; the name, address, and other particulars are entered on it once and for all before it comes into the practitioner's possession; and it acts as an index register of his panel.

With a fairly extensive experience of recording illnesses, both privately and in the out-patient department of a large hospital, I have yet to see a more simple form of record card than the one recently evolved by the Inter-departmental Committee. If Sir William Hodgson (or anyone else) would bring his great talents to bear on evolving a more simple and at the same time useful card, no one, I venture to say, would more cordially welcome it than his colleagues of the Insurance Acts Committee.

Sir William Hodgson was scarcely happy in his quotation from Kipling and the deduction he drew from it. The "colonel's lady" without doubt has all her ailments duly "labelled, ticketed, and docketed" in the case-book of her family doctor, while it is the "Judy O'Grady—her sister under the skin"—who has not up to the present had that advantage. Now the Government steps in and says Judy shall be placed medically on a par with her more fortunate sister. Does any thinking man with the welfare of his profession and patients at heart deny the wisdom of this, or the right of the Ministry to see that it is done?

Similarly with the peer and the pauper, each has his health sheet kept either in the consulting-room of his doctor or in the archives of a board of guardians. The peer takes good care to consult a doctor who keeps records; he wants no haphazard physician with placebos. This leads up to the question of secrecy and how far this cry is genuine. It seems to me the question hardly comes in if the doctor keeps his own records. Does Sir William Hodgson or those who think with him refrain from sending cases of venereal disease and all its sequelae to the best general hospital, where all the details are noted and may be seen by both nurses and attendants? Did he in the old club days refuse to accept clubs which required certificates of sickness? If not, for ever let him hold his pen on this subject.

Much has been made of the time wasted in keeping records. Of course it takes a little time—very little when one is used to it—but in my experience the time is more than saved on some future occasion. The obligation is to keep only such notes of every case treated as in the opinion of the practitioner are likely to be of value to himself or any other practitioner treating the patient subsequently. The discretion is left to the practitioner's own judgement. Is it much trouble to enter the letter "D." in case of digestive disturbances or the letters "R.C." in minor respiratory troubles? These or similar symbols are all that need or are expected to be entered in "trivial" cases. But where does trivial end and serious begin? The "R.C." may become tuberculosis of the lung, the vague "D." may become carcinoma of the stomach, the septic mouth may infect the heart valves, or the neuro-asthenic may become the G.P.I. Let us then make some note, however brief, so that we may learn—those of us at any rate who do not know it all. Also let us keep an accurate summary of all attendances, otherwise when the economy campaign reaches the capitation fee, our negotiators may be "in the soup."

As regards inspection by the Regional Medical Officers, I can only say that I have been assured by the courteous gentleman who has charge of this region that his final instructions from the Ministry were something as follows: "You are a panel doctor going to help with your knowledge and experience other panel doctors, and by so much as you cease to be a panel doctor and become an official by that much will you have failed in your duty." If that is so, why should we call "Wolf" when there is no wolf but only a courteous colleague?

In conclusion I would say—and in this I feel sure Sir William Hodgson will agree—that a more earnest, zealous, or hard working body of men than the Insurance Acts Committee it would be difficult to find, and that any real criticisms of this system, or anything else connected with the working of the Acts, will always be welcomed with both hands.—I am, etc.,

Sheffield, Feb. 14th.

ALEX. FORBES.

Insurance Medical Records.

SIR,—We are pledged to make an honest attempt to keep the new record cards, but have reserved to ourselves the right of criticism in the light of experience. I believe

that many of our anticipated difficulties, whether they be realized or not, can be traced to the fundamental error of attempting to combine for our insured patients visiting lists, daybooks, and clinical life-histories all on one card—a combination never attempted for our private patients.

When the time comes to revise the present Regulations I would like panel practitioners and Panel Committees to consider seriously the following suggestions:

Let the present envelopes remain as index cards and clinical life-histories of our insured patients.

Let the only obligation on the part of the general practitioner, after verifying the correctness of certain particulars, be to enter on these envelopes such clinical notes as he may consider of value either to himself or to succeeding medical practitioners.

Let the law of averages be applied to assist us in obtaining the necessary statistics of attendances and visits, as is being done at the present time in the case of the mileage returns.

Let it be the duty of Panel Committees to find a certain percentage (say 10 per cent.) of practitioners with average practices who would undertake to keep a simple form of loose-leaved daybook for their insured patients, providing either a fortnightly or monthly return of all attendances and visits, these returns, when completed, to be forwarded to the regional referee's office, there to be tabulated.

Let some suitable remuneration be granted from the local medical pool to these public-spirited gentlemen for their labours on behalf of the rest of the profession.

From these compact reliable returns the average number of attendances and visits per insured person for the area could easily be calculated.

Result.—(1) Relief to 50 per cent. of practitioners of much irksome and tiresome work. (2) Less wear and tear of envelopes. (3) Less continuation cards required, and so less bulk. (4) More efficient clinical records; attention directed solely to making them of real value. (5) A compact reliable and easily digested set of statistics in place of a mass of unreliable figures difficult to collect or tabulate. (6) Less local inspection; statistics of attendances and visits would be worked out in regional offices.

Arguments can be adduced both for and against this proposal, but I believe those in favour far outweigh those against, and I ask panel practitioners to give it their serious consideration; it would make for simplicity, efficiency, and reduction of labour.—I am, etc.,

Bratton, Wilts, Feb. 13th.

T. WOOD LOCKET.

Note.—The germ of this suggestion appeared in the second part of an amendment placed on the agenda of the last Panel Conference by Warrington.—T.W.L.

The New Record Cards.

SIR,—I am instructed to forward to you the following resolution which was passed at a meeting of the Kingston-upon-Hull Panel and Local Medical Committee held on February 4th, 1921:

This Committee, having carefully considered the question of the new medical Record Cards and the criticisms which have been fomented against them in the press, and having heard the views of their members who have had five weeks' experience of the working of the system, desires to record its opinion that:

1. The outcry which has taken place against the Records in some press organs is quite unwarranted, probably promoted for interested reasons, and not likely to conduce either to the safety and welfare of panel patients or to the smooth and efficient working of the National Health Insurance Acts.

2. While the system is doubtless capable of improvement in some of its details, it embodies a sound and necessary principle, and, if honestly and thoroughly administered, is calculated to be of great future benefit alike to patients, doctors, and the Ministry of Health.

3. As at the Conference of Local Medical and Panel Committees, held in London on October 21st, 1920, the scheme was discussed, and it was resolved that a fair trial should be given to the new Record Cards; that decision should be loyally accepted and adhered to for at least one year, during which time efforts could be made to collate the experiences of committees and doctors throughout the country with a view to improving some of the details of the present scheme and eliminating any features which may be found to interfere with its usefulness or efficiency.

—I am, etc.,

JOS. NELSON,
Honorary Secretary.

Hull, Feb. 10th.

SIR,—May I be allowed to state that my partners and I have found that the new medical record cards entail very little extra work and we entirely approve of them.

Between us we have a panel of over 2,500. We have placed all our record cards together in cabinets in the

surgery, and find that it is a matter of only a few seconds to ask a patient to produce his or her card, find it in the cabinets, and make the required entries. It is true that clerical errors are prominent in the cards as issued, and we have found that a number of cards are missing. These are easily replaced by continuation-cards. The new cards are only a month old, but we, at any rate, have "got to work" with them.

Not one of our patients has raised any objection on seeing entries made on their cards. At first we were considerably puzzled as to how to proceed on receipt of the new cards, which all arrived together, but a month's trial of them has shown that we were hasty in raising objections.

The point as to whether it is necessary to record every attendance, visit, and certificate has still to be settled. I feel sure, however, that such details are required just to show whether we are earning our money. The cards are on trial, and will no doubt be amended in some way. I am sure that it is very necessary to keep records of all patients, and shall be just as pleased to receive records of those who are trouble some and worry one with nothing wrong, as I shall be to receive records of interesting cases.

A few days in the line of work I intend to keep the record to test the limits of my ability, and I hope others will do the same.

H. VANCE, M.R.C.S., L.R.C.P.

Medical Records.

SIR, At the request of Mr. W. Hodgson in the SUPPLEMENT of Feb. 12th, I am to require a reply to a panel of practitioners to be made to the death stamp upon the cards issued with the new record cards.

The question of panel practitioners in the matter are already settled in the report of the Record Committee. It is the intention of the Insurance Committees to have the cards issued to all practitioners, and to state that all certificates must be entered on the card. Only first and final certificates are required.

It is not necessary to state that all ailments of every kind are to be entered on the card. With regard to clinical notes, I do not think there is an obligation to make any entry on any particular card, but the doctor must make a note of the case as he considers will be of value to himself, or any other practitioner, in the treatment of the patient. A series of symbols is suggested for the recording of important ailments, should the doctor consider it necessary to enter them.

It is required that all attendances and visits are to be entered, and arrangements are provided for summarizing visits each week or month, as well as attendances where the case is very frequent.

The Record Committee considered the "professional secrecy" question, and were satisfied that the arrangements they suggested and which have been set up will provide efficiently against leakage of professional information during transit from doctor to doctor.

As Sir W. Hodgson says, the system is on trial, and if he or anyone else, will devise a more simple system which would be useful and helpful as between practitioner and practitioner in the interests of patients, or, after experience, offer constructive criticisms of this system, the Insurance Acts Committee will welcome them. At the same time I would suggest that those who squeal that the shoes pinch before they have had time to try them on, are never likely to find out where they really do pinch, or to get a comfortable working fit.—I am, etc.,

H. GUY DAIN.

Birmingham, Feb. 15th.

Medical Records in Scotland.

SIR,—The insurance practitioner of to-day is required in Scotland to "furnish" records, and, according to the Scottish Board of Health, in England merely to "keep" records. The Scottish Board have omitted from their Regulations two essential words—"and deliver." To establish the contention of the Board—that there is a definite obligation on Scottish panel-practitioners to send their records to Insurance Committees—the Regulation should read "furnish and deliver." No travesty of the English language can clothe the word "furnish" with a meaning it has not got. If I ask a firm to furnish me with suitable appliances for filling the record cards it will do so; the delivery of the goods is another matter. I shall have to pay carriage. It would, therefore, appear that the Scottish Board are not in any essential point in advance of the English Board, and it becomes a matter for arbitration as to whether the cards are to be delivered by the practitioner or, alternatively, collected by the Board; in addition I submit that if kept and available for inspection in my consulting room I have furnished records and complied with the spirit and letter of Clause 8 (11)—Terms of Service

for Practitioners, etc. Obviously records "furnished" may be delivered by the practitioner, collected by the Board, or available for inspection.

Scottish practitioners would do well to note the letter of the Scottish Board as published in the SUPPLEMENT of February 5th, 1921. No doubt we will in time receive many official documents with a quasi-judicial tone, entirely cold and unsympathetic towards the rural practitioner, indicating that the Scottish Board are drifting towards a policy of trying to enforce the record card regulations according to their own interpretation, and riding rough-shod over the practitioner. It is essential that we should as one man follow the recommendations of the Scottish Insurance Acts Subcommittee, and not transmit records to Insurance Committees until arrangements are made for reimbursement of expenses incurred.

Record keeping should not have begun until all the essentials were in the hands of practitioners. We are temporizing in Scotland until the arrival of the envelope. The scheme of the Interdepartmental Committee has begun in chaos, and is apparently in danger of ending in confusion.

We are told that the records "are designed to afford a continuous record of illness and incapacity." What about age, occupation, and, in the case of women, whether married, single, or widow, with date of such marriage or widowhood? Surely secretaries of approved societies are in a better position than practitioners to supply the details, which do not seem to be connected with a "continuous record of illness and incapacity."

It is quite obvious from the correspondence in the SUPPLEMENT and notices in the lay press that there is a wide divergence of opinion on the question of medical records. As regards the value of purely clinical records there can be no doubt in the mind of any experienced practitioner. We must remember, however, that this is just the beginning; an enlightened Board of Health will at an early date consider the question of embodying the records of welfare and health visitors and records of medical inspectors of school children, so that the logical ideal will be attained, and the envelope of each insured person will contain a continuous record of health, illness, and incapacity from the cradle to the grave.—I am, etc.,

GEORGE R. LIVINGSTON.

Dumfries, Feb. 12th.

Dangerous Drugs Regulations.

SIR,—The Medical Benefit Subcommittee of the Brighton Insurance Committee have had before them, and have very carefully considered, the provisions of the draft Regulations proposed to be issued by the Secretary of State for Home Affairs under the Dangerous Drugs Act, 1920. As a result of this consideration the Subcommittee passed the following resolutions:

1. That the Secretary of State for Home Affairs be informed that the procedure which it is required, in compliance with the proposed Regulations, that insurance practitioners should adopt, will prove, under the unnecessary official interference with everyday practice, so irksome to practitioners that it will be detrimental to the interests of the injured person inasmuch as the consequence will be, in many cases, to deprive the insured person of the drug which may be necessary, and which would otherwise be given, and further if such drug is prescribed, its required advertisement on the bottle or package will have a harmful effect on the patient in many cases.
2. That the insurance practitioner should be allowed, as heretofore, every latitude in determining the drugs considered most desirable for his insurance patient without having to disclose to lay inspecting officials professional matters, and should be responsible to the Minister of Health alone for his actions in this direction.

In the discussion which took place the main points which were emphasized are as follows:

"Article 8 (8) of the terms of service for insurance practitioners stipulates: 'A practitioner is required to supply to a patient where requisite drugs and appliances, which are necessarily or ordinarily administered by a practitioner in person, or are needed for immediate administration or application or needed for use before a supply can conveniently be obtained otherwise under the Regulations.'"

It would appear from the rather vague terms of the draft Regulations, that on every occasion upon which an insurance practitioner is under the necessity of complying with the obligations undertaken as a consequence of the foregoing article, he must make, or cause to be made, in a book kept for the purpose, specific and detailed, and indeed somewhat laboured entries, if the particular drug comes within the scope of these proposed Regulations. It is strongly felt that this will be detrimental to the interests of insured persons, inasmuch as the practitioner rather than comply with the necessary clerical procedure may

refrain from giving the necessary drug. I am aware that Sir Edward Troup, Permanent Under Secretary at the Home Office, in a letter which appeared in the *Times* of February 9th, stated as follows:

"In several important respects the Draft Regulations have been misunderstood. It has been suggested, for instance, that a doctor is required on each occasion on which he gives a hypodermic injection of morphia, or otherwise administers any of the drug, to enter the fact in a book. This is not so. The Regulations require certain records to be kept in cases where drugs are supplied, and these apply to doctors who supply medicines to their patients, as well as to chemists who supply them on a doctor's prescription. But there is no requirement that a record has to be kept of a personal administration of the drugs by a doctor."

If Sir Edward Troup's interpretation on this point is the correct one, then it is respectfully submitted that the draft Regulations should be so amended as to make the matter quite clear.

Provided an insurance practitioner has occasion to prescribe medicines containing an amount beyond the statutory limit of any of the drugs set forth in the proposed Regulations, then the fact must be advertised on the bottle or package containing such drugs. Indeed, the article defining the "application" of the Regulations in connexion with morphia, cocaine, ecgonine, and diamorphine, when read in conjunction with Article (8) of the Regulations, is rather confusing. However, it is suggested that a bottle or package loudly proclaiming to the insured person the fact that it contains a certain percentage of a dangerous drug is not conducive to that serene frame of mind which, in the interests of the patient himself, his medical attendant would wish him to cultivate.

It is hoped that your influential journal will see its way to support the views above expressed and make every endeavour to get the proposed Regulations so amended as to entirely safeguard the interests of the country's insured population—I am, etc.,

JNO. CAMPBELL,

Acting Clerk to the Insurance Committee for the
Borough of Brighton

February 11th

Medical Benefit.

SIR,—I agree with everything in the letter you publish from Dr. Eates, of the London Panel, under date January 13th, sent to the Minister of Health. I believe every panel practitioner in the country could tell the same tale of insured persons being removed from his list through errors either of the Insurance Committees, the approved societies, or both. People are removed, and when the doctor tells them they can no longer be attended as panel patients they are surprised—they say they are stamping their cards, and produce them for us to see. They urge there is a mistake, and very often there is. I have been told officially that it is the doctor's duty to satisfy himself that a person is entitled to benefit. Why the doctor? To do this involves a weary correspondence with the Insurance Committee and the approved society, and very few men have the time to do it—they simply "let things go." It does not so much matter for a townsman with a large panel, but the country doctor, with a small panel and most of his patients many miles away, loses not only his capitation fees but his mileage.

Like Dr. Eates, I consider that our record cards supplied under the new Regulations are "woefully incomplete," and the reason given by the Northumberland Insurance Committee is that the supplies have run short at the Ministry of Health.

I hold that when an insured person is removed from a doctor's list, he should be told at the time in plain language which he can understand that until he is restored to that list he must pay for his medical attention. The term "ceased to be insured" is too vague, and it should be explained why he has "ceased to be insured." I often get such a removal notice, and I know the person is in regular insurable employment, but unless I give myself infinite trouble writing letters and making inquiries I never find out, and then I hear it was all a mistake, after losing possibly several quarters' fees. Why should we be penalized through the mistakes of others? I have long pointed out that all the penalizing falls on the doctor and never on the Insurance Committee, the approved society, nor the insured person. We not only have our own clerical work to do, but a vast deal that should belong to others.

I have definitely come to the conclusion that these matters are becoming worse. It would seem that with the increase of officials all round the work of the Insurance Act is less efficiently performed than it was in its early days—I am, etc.,

Felton Northumberland, Feb 7th

ROBERT A. WELSH.

Evening Surgery.

SIR,—I was very glad to see Dr. Wightman's letter, in the SUPPLEMENT of February 5th, about evening surgeries in the country. As regards my own practice, which is a very scattered one, there has never been an evening surgery and no grounds of complaint have arisen on that account. Any urgent case is seen at the surgery at any time, and it is much more convenient for the great bulk of my patients, who reside several miles away, to be seen at their own homes. I think we should hold out strongly against compulsory evening surgeries. Surely we should be allowed a short space of leisure in the evenings after a strenuous day's work. We have precious little time as it is that we can call our own, our days and nights being often taken up with work.—I am, etc.,

Caxton nr Cambridge, Feb 8th

P. HUGHES DUDLEY.

LOCAL MEDICAL AND PANEL COMMITTEES.

BIRMINGHAM.

A MEETING of the Birmingham Panel Committee was held on February 1st, with Dr. DAIR in the chair. The Birmingham Insurance Committee intimated that the "datum line" in connexion with the scrutiny of prescriptions was, as suggested by the Panel Committee, fixed at 75 per cent. above the average cost of prescriptions issued during the previous quarter. In reply to a letter from the Dewsbury Panel Committee suggesting the giving up of the use of the telephone by practitioners as a protest against the new rates, it was decided to take no steps.

The Secretary was instructed to write, protesting against the Dangerous Drugs Act, to the Minister of Health, the General Medical Council, the Society of Surgeons and Physicians, to the Members of Parliament, University representatives in Parliament, and Sir Gilbert Barling.

It was decided to refrain from asking for a special conference of Panel and Local Medical Committees to consider the record cards, as had been requested by the Cheshire Panel Committee.

DEVON COUNTY.

The following resolution was passed at a meeting held on February 11th, 1921:

That the Devon County Panel Committee recognizes that the keeping of some form of continuous medical record is not only desirable in the interests of patients, but constitutes one of the duties of panel practitioners; and that such duty was definitely considered as part of the service to be paid for when the case for increased remuneration was put before the Arbitration Board in 1920, and that while it does not approve the present form as best suited for its purpose, the Committee advises Devonshire practitioners loyally to carry out the decision of the Conference of Representatives of Panel Committees in 1920 and to give the new record forms a trial before passing a formal opinion thereon.

Naval and Military Appointments.

ROYAL NAVAL MEDICAL SERVICE.

The Admiralty. Surgeon:
Lieut. Commanders
H E Scargill to be
Lieutenants J H B
Hosp. tal, G V. Hobbs
resigning

ARMY MEDICAL SERVICE.

Colonels J. V. Forrest, C.B., C.M.G., and S. L. Cummins, C.B., C.M.G., retire on retired pay

ROYAL ARMY MEDICAL CORPS.

Lieut. Colonel M P Corkery, O.B.E., is placed on the half pay list

DSO, retires on retired pay November

rank of Colonel (substituted for notification in the *London Gazette*, November 12th 1920)

Major H G Pinches retires on retired pay, and is granted the rank of Lieutenant Colonel

Major J A Manifold, DSO, to be an assistant Professor, Royal Army Medical College

The following relinquish the acting rank of Lieutenant Colonel: Major H T Wilson, DSO, Captain and Brevet Major R E Barnes, Major C R M Morris, DSO

The following Captains to be Majors: Brevet Major J A Manifold, DSO, S.S. Dyer, W H O'Riordan, M.C., T V Benson (acting Lieut. Colonel) W. P. MacIntyre, DSO, O.B.E., (acting Major) R C Priest, Brevet Major S. Lomax, DSO, (temporary Major) A D Stirling, DSO, G P Taylor, DSO, M.C., R C Paris, E C Lambkin, DSO, M.C., O W MacIntyre, DSO, M.C., Brevet Major M J Williamson, M.C., G C MacIntyre, M.C., J J D. Roche, H F Joynt, A.S.J., J R Yourell, P. G M Lacey, DSO, M.C., J. J. H. Beckett, W B Bennie, M.C., W. Matheson, O.B.E.

Captain L F K Way, DSO, retires, receiving a gratuity, January 15th 1921 (substituted for notification in the *London Gazette*, January 13th 1921)

The notification in the *London Gazette* of January 13th, 1921, regarding Major J Startin, M.C. is cancelled. The name of Captain Geoffrey Dawson Gripper is as now described, and not as in the *London Gazette* of May 9th 1919

To be Captains: Lieutenants (Temporary Captains) P. A. Stewart, J. C. Collier, W. I. Pitt, J. Powell, G. W. H. Shaw, W. C. Mackinnon. To be temporary Captains: P. W. Harlow, late temporary Captain, with seniority from December 12th, 1914; temporary Lieutenant O. T. J. C. de B. Clavie.

The following officers relinquish their commissions: Temporary Captains (a) certain the rank of Captain: R. Grant, J. Monroe, L. V. Gail, C. P. Strange.

ROYAL AIR FORCE.

Medical Branch.

The following are granted short service commissions as Flight Lieutenants, retaining their present seniority, with effect from February 1st, 1921: P. E. Duff, C. McC. Jones. Flight Lieutenant H. M. Nicholson resigns his short service commission and is permitted to retain the rank of Captain. P. B. Humphreys (Major R.V.M.C.T.F.) is granted a temporary commission as Flight Lieutenant and to be honorary Squadron Leader.

INDIAN MEDICAL SERVICE.

Major H. H. Pitt, M.D., F.R.C.S., Professor of Operative Surgery, King Edward Medical College, Lahore, has been granted combined leave for 6 months.

Colonel O. Tate, M.B., Assistant Professor of Midwifery, King Edward Medical College, Lahore, appointed to act as Professor of Operative Surgery in the College in addition to his own duties during Tate's absence on leave of Major Holt.

Major W. J. Patton, M.D., has been placed on special duty under the Director General I.S.M.

Major J. McLeary is appointed to hold charge of the current duties of the office of District Surgeon, Eastern Rajputana States, in addition to his own duties (December 1st, 1920).

The following officers have been appointed to the service permanently, with effect from March 14th, 1920: H. Z. Shah, P. C. Farnham, B. Sahai, D. B. Thapar.

The following officers have been permitted to retire from the service, with effect from the dates specified:—Lieut. Colonels: J. L. Martin, October 1st, 1920; H. H. Gaster, November 9th, 1920; J. Dwyer, F.R.C.S., November 27th, 1920; C. A. Johnston, C.B., D.S.O., October 1st, 1920.

In the list of officers promoted to be Lieutenant Colonels, published in the issue of February 5th, p. 30, the name of G. Fowler was inadvertently omitted.

TERRITORIAL FORCE.

Royal Army Medical Corps.

Major W. T. Rose, M.D., to be Lieutenant Colonel and command 1st Northamptonshire T.F. Coy. Station Hospital, Colchester. Captain C. E. H. A. Roberts, O.B.E., R. G. Badenech, G. T. Wilson, D.S.O.

DIARY OF SOCIETIES AND LECTURES.

Medical Society of London, 11, Chandos Street, W.1.—Mon., 7.30 p.m., Lecture by Mr. George E. Gask, C.M.G., D.S.O., The Surgery of the Lung and Pleura.

Medical Society of London, 11, Chandos Street, W.1.—Emeritus Lectures, 7.30 p.m., Sir A. Pearce Gould: Surgery. Fri., Sir R. Douglas Ross: Pathology.

Royal College of Physicians, Pall Mall East, S.W.—Tues. and Thurs. 5 p.m., Dr. Martin Fleck: Murrey Lecture.—Respiratory Physiology in Relation to Health and Disease.

Royal College of Physicians, Lincoln's Inn Fields, W.C.—Mon., 5 p.m., Terms and Title Lecture by Professor J. H. H. Evans: The Arterial System of Veins in their Association with Surgical Arteries.

Royal Society of Medicine.—Section of Medicine: Guy's Hospital, Tues. 4.30 p.m., Text and Demonstrations by the Physicians and Assistant Physicians; 5.30 p.m., Dr. G. H. Hunt: Cardiac Physiology; Mr. J. M. H. Campbell: Causation of Dyspepsia; Dr. J. A. Ryle: The Practice of Medicine. Section of Tropical Medicine: Thurs. 5 p.m., Election of Officers and Council; Dr. Donald A. Ross by Sir Leonard Rogers; Paper by Dr. J. Gordon Thomson and Dr. A. Robertson: Laboratory Reports in the Diagnosis of Suspected Typhoid; Demonstrations by Professor Lester and others. Section of Urology: Thurs. 8.30 p.m., Clinical and Pathological Evening; specimens will be shown. Section for the Study of Disease in Children: Fri., 4.30 p.m., Discussion on the Diagnosis and Treatment of Congenital Syphilis and its Effects, to be opened by Sir H. D. Holleston and Mr. O. L. Addison. Section of Epidemiology and State Medicine: Fri., 8.30 p.m., Dr. R. M. F. Picken: Epidemiology of Measles in a Rural and Residential Area. Clinical, Medical, and Surgical Sections: Fri., 8.30 p.m., Adjourned Discussion on the Medical and Surgical Treatment of Graves's Disease; Mr. Donald Armour, Dr. J. M. H. Campbell, Mr. W. H. C. Romanis, Mr. A. J. Walton, Professor Earle, and others.

St. John's Hospital, 49, Leicester Square, W.C.2.—Thurs., 6 p.m., Dr. W. Griffith: Chesterfield Lecture—Diseases of the Skin Appendages.

POST-GRADUATE COURSES AND LECTURES.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION, Royal Maternity and Women's Hospital.—Wed., 4.15 p.m., Dr. S. J. Cameron: Obstetrical Cases.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, W.C.—Thurs., 4 p.m., Dr. T. T. 4.30 p.m., Dr. Stirling.

MANCHESTER: ANCO Treatment of CC. no.—Sat., 3.30 p.m., Dr.

MANCHESTER HANI Chisholm: The

MANCHESTER ROYAL INFIRMARY.—Thurs., 4.30 p.m., Mr. P. R. Wrigley: Cholecystitis.

MANCHESTER: ST. MARY'S HOSPITALS (Whitworth Street West Branch).—Fri., 4.30 p.m., Dr. Lacey: Toxaemia of Pregnancy.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westminster Street, W.1.—Mon., 5.30 p.m., Dr. Hamill: Myocardial Disease.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen Square, W.C.1.—Daily (except Wed. and Sat.) 2 p.m., Out-patient Clinics. Lectures, 3.30 p.m.—Mon., Dr. K. Wilson: Hysteria; Tues., Dr. Collier: Diseases of the Cranial Nerves; Thurs., Mr. Scott: Disturbances of the Vestibular System; Fri., Dr. G. Stewart: Affections of the Pituitary Gland.

WEST LONDON POST-GRADUATE COLLEGE, Hammersmith, W.—Daily, 10 a.m., Ward Visits; 2 p.m., In- and Out-patient Clinics and Operations. Lectures, 5 p.m.—Mon., Dr. G. Stewart: Locomotor Ataxia; Tues., Dr. Burnford: Functions of the Digestive Tract; Wed., Mr. Arnour: Abdominal Tumours; Thurs., Mr. Edwards: Rectal Surgery; Fri., Mr. Addison: Carcinoma of the Breast.

APRIL.

14 Thurs. Worcestershire and Herefordshire Branch: British Medical Association Lecture by Mr. P. L. Daniel, F.R.C.S., on the Differential Diagnosis of Acute Abdominal Conditions.

APPOINTMENTS.

BURGESS, Arthur H., F.R.C.S. Eng., M.B., M.Sc. Vict., Professor of Clinical Surgery in the University of Manchester.

McDONALD, Niel, O.B.E., M.B., Ch.B. Vict., M.R.C.S., L.R.C.P. Lond., Anaesthetist to the Great Northern.

MACFARLANE, William, O.B.E. (Military), Assistant Medical Officer of Health and Assistant Officer for Birkenhead.

MACGARRON, R., M.B., Ch.B., Assistant Medical Officer to the Stobhill Hospital, Springburn, Glasgow.

SCHAUER, J. W., M.B., D.P.H. Dub., Assistant Health Officer (Rural), Singapore.

STANUS, H. S., M.D., M.R.C.P. Lond., Medical Adviser to the Board of Inland Revenue.

ST. THOMAS'S HOSPITAL.—The following appointments have been made:—Casualty Officers and Resident Anaesthetists: G. A. Back, M.R.C.S., L.R.C.P., E. D. Granger, M.B., B.S. Lond., C. K. J. Hamilton, M.C., B.A., M.B., B.Ch. Oxon., J. T. S. Hoey, M.A., M.B., B.Ch. Oxon., P. T. Liang, M.A., B.Ch. Cantab., D.T.M., A. D. Whitelaw, B.A. Cantab., M.R.C.S., L.R.C.P., Resident House-Physicians: L. B. Maxwell, O.B.E., B.A. Cantab., M.R.C.S., L.R.C.P., A. T. Hawley, B.A. Cantab., M.R.C.S., L.R.C.P., G. M. Kendall, M.B. Cantab., Resident House-Physician (for Children): F. B. Hobbs, B.A., M.B., B.Ch. Cantab., Resident House-Surgeons: D. G. Garnett, B.A. Cantab., M.R.C.S., L.R.C.P., W. A. Low, M.C., M.R.C.S., L.R.C.P., Obstetric House-Physicians: (Senior) C. D. Maitland, M.B., B.S. Lond., F.R.C.S.; (Junior) E. S. Orme, B.A. Cantab., M.R.C.S., L.R.C.P., Clinical Assistants: (Throat) F. G. Wood, M.A., B.Ch. Cantab.; (Skin) S. H. G. Humfrey, B.A. Cantab., M.R.C.S., L.R.C.P.; (Ear) R. H. O. B. Robinson, B.A., M.B., B.Ch. Cantab.; (Children's Medical) J. A. P. Shaw, B.A. Cantab., M.R.C.S., L.R.C.P., R. N. L. Symes, M.R.C.S., L.R.C.P.; (Tuberculosis Department) G. D. C. Tracey, B.A. Cantab., M.R.C.S., L.R.C.P., K. H. Telfer, M.C., B.A. Cantab., M.R.C.S., L.R.C.P.; (Electrical and X-Ray Department) B. Shires, M.B., Ch.B. Edin.; (Orthopaedic) C. L. C. Burns, M.R.C.S., L.R.C.P.; (Mental) C. J. Thomas, M.R.C.S., L.R.C.P.; (Electro-cardiograph) B. T. Parsons Smith, M.D. Lond. Several other gentlemen have received extensions of their appointments.

BIRTHS, MARRIAGES, AND DEATHS.

The charge for inserting announcements of Births, Marriages, and Deaths is 9s., which sum should be forwarded with the notice not later than the first post on Tuesday morning, in order to ensure insertion in the current issue.

BIRTH.

CRAWFORD.—February 10th, 1921, at 245, Lower Circular Road, Calcutta, the wife of Lieut.-Colonel V. J. Crawford, D.S.O., R.A.M.C., of a daughter.

DEATH.

GARD.—On February 13th, at a nursing home, William John Gard, M.R.C.S. Eng., L.R.C.P. Lond., beloved husband of Julia Mary Gard, of 2, Clarendon Terrace, Stoke, Devonport, aged 68 years. Friends please accept this the only intimation.

*Practise Abroad.*⁸ The first edition was issued in January, 1910, and a revised and expanded edition in August of the same year. The report is founded either on answers received from the authorities of the several countries or on information in the possession of the General Medical Council. The new, fifth, edition has been brought up to date, and British practitioners who are thinking of going abroad will find in this volume the most comprehensive and accurate information available as to the conditions of practice in other countries. Requirements, however, are liable to change, and the registrar, Colonel Norman C. King, has been careful in all cases to supply the name of the official from whom the necessary forms and latest details can be obtained. This very necessary precaution should always be taken.

Under the auspices of the Carnegie Endowment for International Peace a valuable series of economic studies of the war is being published, under the general editorship of Dr. David Kinley, professor of political economy in the University of Illinois. It includes such subjects as the early economic effects of the war on Canada, Chile, and Peru, the financial history of Great Britain in 1914-18, British war administration, negro migration during the war, the Germans in South America, Government war contracts. The volume now received is on prices and price control in Great Britain and the United States during the world war,⁹ and is by Dr. SIMON LITMAN, professor of economics in the University of Illinois. His study of the question shows that legal action on the whole has had little effect in preventing or removing the evil practices that have called forth so much popular denunciation; and the author has included detailed discussions, of much interest, on such matters as causes of the rise in prices, profiteering, and industrial unrest. Although each generation, like each individual, must learn in large measure from its own experience, nevertheless there are in every age some minds able to exert an influence in a new crisis in the direction of sanity and safety by their studies of similar experiences in the past; and to that extent this and other volumes of the series will, it is hoped, have a permanent value.

In *Lays by the Way* Dr. R. B. GREAVES¹⁰ of Sheffield has joined the ranks of medical men who have found expression for their experiences in verse. In the twenty-one short poems there are many touches that will appeal to his silent brethren, particularly that entitled "The Doctor."

APPLIANCES AND PREPARATIONS.

Modified Duval's Lung Forceps.

MR. BRYDEN GLENDINING, M.S., F.R.C.S. (Aspley Guise, Beds), writes: When using Duval's special lung forceps in chest cases during the war I was agreeably impressed with their extremely sensitive and at the same time assured, non-slipping grip, and came to employ them largely in abdominal surgery, where their tenacious but delicate hold proved invaluable, notably for holding or

the tray shown in the accompanying illustration. Such an appliance should be simple, stable, and easily rendered aseptic; the tray will be found to meet these requirements. Dr. H. A. Ellis has suggested to me that it would

be of more value to laboratory workers if the spaces were adapted to hold slides and if a holder for test tubes were added, and these alterations have been made. The tray has been made to my design by Messrs. Allen and Hanburys, Ltd., 48, Wigmore Street, London, W.1.

ROYAL MEDICAL BENEVOLENT FUND.

At the meeting of the Committee held on February 8th seventeen cases were considered, and £245 voted to fifteen applicants. The following is a summary of some of the cases relieved:

M.R.C.S. Eng., aged 80, married. Suffers from facial neuritis following paralysis. Dependent on daughter, who supplements her income by taking paying guests. Applicant receives the old age pension. Voted £15.

Widow, aged 64, of L.S.A. Lond. who died in 1911. Applicant has a son, aged 44, of M.B., C.M. Glas. who died in 1909. Applicant left with three children. She acts as a companion help at £60 per annum. Her eldest son is self-supporting, but she has to pay part of board for second boy, aged 17, who is an engineer's apprentice. Asks £12 in twelve instalments. Voted £25.

Widow, aged 44, of M.B., C.M. Glas. who died in 1909. Applicant left with three children. She acts as a companion help at £60 per annum. Her eldest son is self-supporting, but she has to pay part of board for second boy, aged 17, who is an engineer's apprentice. Asks £12 in twelve instalments. Voted £25.

Widow, aged 54, of L.S.A. Lond. who died in 1911. Applicant has a son, aged 44, of M.B., C.M. Glas. who died in 1909. Applicant left with three children. She acts as a companion help at £60 per annum. Her eldest son is self-supporting, but she has to pay part of board for second boy, aged 17, who is an engineer's apprentice. Asks £12 in twelve instalments. Voted £25.

Widow, aged 54, of L.S.A. Lond. who died in 1911. Applicant has a son, aged 44, of M.B., C.M. Glas. who died in 1909. Applicant left with three children. She acts as a companion help at £60 per annum. Her eldest son is self-supporting, but she has to pay part of board for second boy, aged 17, who is an engineer's apprentice. Asks £12 in twelve instalments. Voted £25.

Widow, aged 54, of L.S.A. Lond. who died in 1911. Applicant has a son, aged 44, of M.B., C.M. Glas. who died in 1909. Applicant left with three children. She acts as a companion help at £60 per annum. Her eldest son is self-supporting, but she has to pay part of board for second boy, aged 17, who is an engineer's apprentice. Asks £12 in twelve instalments. Voted £25.

Widow, aged 54, of L.S.A. Lond. who died in 1911. Applicant has a son, aged 44, of M.B., C.M. Glas. who died in 1909. Applicant left with three children. She acts as a companion help at £60 per annum. Her eldest son is self-supporting, but she has to pay part of board for second boy, aged 17, who is an engineer's apprentice. Asks £12 in twelve instalments. Voted £25.

Messrs. Oliver and Boyd announce for early publication a third edition (rewritten and greatly enlarged) of *The Clinical Study and Treatment of Sick Children*, by Dr. John Thomson.

At the request of the League of Red Cross Societies a large typhus research hospital will be established in connexion with the new American Red Cross Hospital recently opened at Wilmo.

retracting the uterus, appendages, cysts, small tumours, and even gut, when applied over gauze. The original model has a triangular head, of which the angles are too prominent and the bite wider than necessary. Messrs. Allen and Hanburys have therefore modified it for me by removing the sharp angles of the jaws, increasing the length of the instrument, making it more suitable for deep abdominal work, and fitting the bowed end-lock, which prevents sutures getting caught up between the finger rings as in the ordinary pattern of forceps.

A Tray for Tuberculin Administration.

Mr. F. E. GUNTER (London, W.C.) writes: Finding the need of a simple rest or tray for the impedimenta which one uses in giving tuberculin injections, I have designed

ASTLEY COOPER AND HUNTERIAN PRINCIPLES.

SIR CHARTERS SYMONDS'S HUNTERIAN ORATION.

The Hunterian Oration was delivered before the Royal College of Surgeons of England on February 14th, the anniversary of Hunter's birth, by Sir Charters J. Symonds, K.B.E., O.B., consulting surgeon to Guy's Hospital, who took as his main subject, "Astley Cooper and Hunterian principles." After a preliminary tribute to the memory of Hunter, the great biologist and surgeon, the orator named some of Hunter's pupils who left their mark on surgery and became teachers in the schools. He then set out to trace in the career of one distinguished pupil—Astley Cooper—the influence of Hunter's teaching, and to show how the principles laid down were expanded and applied by one who was, perhaps, the best exponent of the application of Hunter's teaching and one who did more than any other surgeon of his time to stimulate inquiry.

Early Career.

Astley Cooper had just completed his 16th year when he arrived in London in August, 1781, to become apprenticed to his uncle, Mr. Cooper, at that time surgeon to Guy's Hospital. He soon became a favourite in the household of Mr. Cline, where he lived, and shortly afterwards, at his own request, he was transferred as apprentice to Cline, a circumstance that had a far-reaching effect on his future. Cline, aged then about 39, was a surgeon at St. Thomas's Hospital; he was a follower of Hunter, carried out his principle, and his teaching, followed his experimental methods, was a good practical surgeon, and a man of sound judgement. At Cline's suggestion, no doubt, Astley Cooper began attendance at Hunter's lectures, and had the priceless advantage of talking over the subject with his master and with other apprentices, one of whom interested him in botany and another in physiology. In his indentures it was provided that he might spend a session in Edinburgh, and thither he went in October, 1787. He carried introductions to the leading professors, whom he was anxious to see and hear. He was by this time a good anatomist, and moreover had spent much time at the Leids and had made careful notes of the cases, so that he was in a position to discuss both anatomical and surgical questions. From his frank and courteous manner, free from pretension, he was well received, and was made a member of the famous Royal Medical Society, and offered the presidency should he return. He made good use of the eleven months, spending his time in the infirmary, making notes of the cases, and attending lectures by Monro and others. At Edinburgh he learned order and system, for which the teaching has always been famous, and under this guidance he planned a method of examining cases of disease which led to the surest and safest mode of forming a diagnosis, and this he pursued throughout his life, to the advantage of his teaching and his practice.

In 1789 Astley Cooper was appointed demonstrator of anatomy at St. Thomas's, and two years later (at the age of 23) he was asked by Cline to take a share in the lectures on anatomy and surgery. Hitherto the subjects of anatomy and surgery were combined in the same lectures, a plan which Astley Cooper considered injurious to both. After some hesitation Cline agreed to their separation. Cooper now resolved to devote the next three years solely to improving his knowledge of anatomy and surgery, without endeavouring to amplify his income from the lectureship by seeking private practice. Disappointed to find that the class at his first course of lectures was inattentive and decreasing in numbers, he concluded it was necessary for his pupils to have a considerable knowledge of surgery before they could comprehend the principles enunciated by Hunter. He at once changed his method, and with immediate success. Cases of disease and injury were brought before the class, the cause and nature of the disease or accident described, with the appropriate treatment, and afterwards the physiological and pathological bearings applied and further illustrated by morbid specimens and

experimental results. This method he pursued throughout his forty years, enriching his lectures with cases from his own experience, and as this widened the lectures became more and more valuable. But never did he lose sight of the scientific side or relapse into the method of earlier lecturers, who dealt with cases only. Always inquiring by dissection, by study of disease in the living and the dead, and by experiment, he was constantly improving his teaching. The lessons to be learnt from such vast inquiry were brought to the service of his class, and each year further light was thrown upon old subjects, and not from second-hand knowledge, but from the actual observation of the teacher himself.

So successful had his lectures become in his second course that when he began the third in 1793 the number of entries had doubled. In this year, at the age of 25, he was appointed lecturer at Surgeons' Hall. To improve further the education he very soon after his appointment promoted a society, confined to the pupils of Guy's and St. Thomas's Hospitals, where cases of interest were shown and discussed. This existed for several years, and was of particular value to the younger men, for the discussions at the Physical Society were beyond the range of any but the senior members of the schools. In a word, he devoted the first three years to the welfare of the students, and when one adds his personality, the buoyant spirits, the sense of humour, the hearty laughter, his readiness to help in their work, and his kindly advice and often assistance in more substantial ways, is it any wonder that he was sought after as a teacher and beloved as a friend? For nine years he continued these demonstrations and lectures, pursuing without intermission his studies in anatomy, comparative anatomy, and physiology. He had gradually obtained private practice, and by the end of the period his income from this source was said to amount to £1,000. In 1800 he was appointed surgeon to Guy's Hospital, thus securing the acme of his ambition at the age of 32. He was well equipped for the position, for though he could not have performed many operations, he had acquired from his dissections such a knowledge of anatomy as would enable him to work with accuracy and speed, and from his experiments on animals a refinement of technique not possessed by any of the other competitors.

Inquiry by experiment and the acquisition of dexterity by operating on animals is (Sir Charters Symonds continued) unfortunately restricted in our country to an extent that has for long checked advance in surgery. Operation on the dead cannot compare with that on the living, even if only on one of the lower animals. In the days of Astley Cooper, when anaesthesia was unknown, time was of the essence of success and of mercy. It was said by one of his colleagues that Astley Cooper could operate as well with an oyster knife as another surgeon with the best out of Landry's shop. This raises the important question of operations on living animals as part of the training of a surgeon. In certain branches of surgery this would be most valuable, and in one at least—operations on the brain—it seems essential. Harvey Cushing, than whom no better authority could be quoted, urges this practice in a recent essay. To learn how to arrest haemorrhage, to handle the brain without injury, to trophine a thin bone without harm to the meninges, to expose any given part by the most direct route, are steps in technique which should be acquired before operating on the human subject. Take, again, operations on the eye, intestinal suturing, or, more important still, suture of the common bile duct and of the ureter, and the suture of arteries—will anyone deny that to approach such operations after adequate practice on living animals cannot but lead to better technique and greater success? Is it not in the interest of the public that facilities should be given to those preparing for important surgical positions to acquire such experience, especially when anaesthesia removes all reasonable objection?

Astley Cooper as Teacher and Surgeon.

Astley Cooper was undoubtedly a great teacher, and in this regard probably had a wider influence than anyone of his time. He no doubt possessed a natural gift for teaching, but this would not have gained him the position he obtained in this respect had it not been for his industry and his determination to enunciate no doctrine unless proved by observation and experiment. He was not a

genius in any sense, and he himself attributed his success entirely to his industry. He had clear ideas as to how knowledge should be acquired, and constantly impressed upon his class the importance of personal observation. He recognized the evil effect of too much teaching, and inculcated personal observation of the processes of Nature.

As a surgeon Astley Cooper's name will always be associated with the ligature of arteries, for he it was who first put a ligature on the carotid; he was one of the earliest to tie the external iliac, and the only surgeon of his time to ligature the aorta. From his earliest days as an apprentice, and all through his life, he carried on experiments of all kinds, and to him was largely due the demonstration of anastomotic circulation. Hunter had ligatured the femoral for the cure of popliteal aneurysm in 1785, when Astley Cooper was in the first year of his apprenticeship to Cline. No doubt master and pupil talked over the revolution in surgery which had saved so many lives, and saw the application of the principle to other situations. During the years that followed he tied all the main vessels in dogs and other animals to prove the truth of the anastomotic circulation. Both carotids were held to be essential to the integrity of the brain in man and animals. The fallacy was soon dismissed as far as dogs were concerned, for he tied both vessels simply and simultaneously without ill effects, and later combined ligature of both carotids with double ligature of the vertebrals. This was generally fatal, but one dog at any rate survived. The performance of such a feat in half an hour was a tribute to the operator's accurate anatomy and technical skill. It was his custom also to ligature the carotid at his lectures to demonstrate the safety as regards the brain. It was, however, generally considered that such an operation in man was "impracticable or would be injurious to the functions of the sensorium." Cooper, however, had found a case where one carotid had been obstructed by disease, and Dr. Baillie had communicated an example of complete obstruction of one and partial of the other carotid without ill effects. The defence of the operation put forward by Travers after his own operation shows the controversy that existed, and emphasizes the boldness of Cooper's undertaking.

The opportunity long anticipated at last arrived, and it was on November 1st, 1805, that he ligatured the common carotid in a woman. It was an advanced case of aneurysm, and occupied so large a space that it was just a question whether there was room for a ligature between the sac and the clavicle. In the skilled hands of Astley Cooper, however, that was accomplished which few would have attempted. The patient died from suppuration of the sac twenty days later. Astley Cooper was not discouraged, for he had established two points: that the carotid could be safely tied and without injury to the brain. In reading the account before the Medico-Chirurgical Society on January 29th, 1806, he says: "The failure was due to the operation being too long delayed, and it will not prevent my performing it in any case in which the disease is somewhat less advanced." It is not difficult to imagine the criticisms that would be levelled by those who thought such an operation unjustifiable.

The second opportunity came on June 22nd, 1808, and was a complete success. In reading this case before the same society reference was made to experimental ligature "many years ago." On the death of this patient, thirteen years later from apoplexy, the brain was obtained, and a drawing is given in *Guy's Hospital Reports*, vol. i. Both these operations were carried out in the presence of several surgeons of the hospitals and some visitors, and one cannot but admire the courage of the operator's convictions. In both instances examination showed that no injury had been sustained by neighbouring structures. On the same day on which the second operation took place he ligatured the external iliac in an urgent case in which rupture was imminent. Eighteen years later the specimen was obtained at considerable expense and trouble, for the man lived in the country.

Finally came the culmination of this work in the ligature of the aorta. The operation was performed on June 25th, 1817, by the transperitoneal route. In referring to his experiments, when reading the paper on ligature of the carotid, he says: "Lastly, I was anxious to ascertain when even the aorta was tied if the blood would still find

its course by anastomosis." This he had demonstrated in dogs, and had repeated the experiments two years before—that is, in 1815. "The animal," he says, "survived the experiment and maintained his usual health." Again it was unfortunate that the case was an advanced one, and the man greatly reduced by hæmorrhage. The aneurysm was of immense size and filled the left iliac fossa; operation by the route adopted on animals was impossible, and he determined, rather than that the man should be left, to open the abdomen, displace the intestines, and secure the artery above the bifurcation. With his usual solicitude he explained the position to the patient, who replied, "Sir, I leave myself in your hands." With that dexterity which was the outcome of his experimental inquiries, he then placed the ligature, without, as it proved, any injury to other structures. Though the man lived only forty hours the right limb had recovered its warmth and sensation, but the left—the affected side—remained cold and discoloured. This he considered was due to the pressure of the large aneurysm interfering with the anastomosing vessels.

Thus he had broken new ground, had thought out the details of possible operations, had by experiment on animals proved that so far as they were concerned success was obtained, and therefore might be anticipated in man. "The secret of success in life is for a man to be ready when his opportunity comes."

Hunter and Cooper.

The portrait by Sir T. Lawrence (concluded the Orator) exhibits Astley Cooper somewhere approaching 60, and is considered the *chef d'œuvre* of this great painter. It is interesting to compare it with that of Hunter; both are looking up and into the future, both see much to be done—Hunter the philosophic genius, and Cooper his great pupil, ready for any emergency. Both Hunter and Astley Cooper fully gave of their knowledge to others, and were not concerned who discovered the truth so long as it was found. Truth to them was bigger than person or school.

Cooper died in 1841 at the age of 74, having extended and upheld the reputation of British surgery for half a century, and was buried beneath the chapel of the hospital he loved so well and whose fame he did so much to extend. By his will he founded a triennial prize, and it is significant that he directed that the first subjects for inquiry should be upon the thyroid, the spleen, the thymus, the suprarenal capsules, and the state of the blood and blood vessels in inflammation—all subjects on which he had himself made observations and conducted experiments. He foresaw that future workers, better equipped, would unravel the secrets which had baffled him. The Hunterian era awoke in the minds of men a desire to explore the old ground by new methods and to unearth the truths so long concealed. There was a spirit of adventure like that which animated the Elizabethan explorers, the ambition of the healthy human intellect to extend its range of vision and knowledge. To Hunter belongs the credit of the discovery of this new world. He it was who lighted the torch, and I hope I have shown that Astley Cooper was amongst those who first carried it forward in the race, kept it alight, and then passed it on not only undiminished, but burning with a brighter flame; and so when his course was run the goal was nearer for the part he had taken. "After brief life men die, and like runners in a race hand on their torch to another."

At the meeting of the London County Council on February 15th, Captain Swinton moved that it be an instruction to the Education Committee forthwith to confer with the Improvements and Building Acts Committees on the question of a site at Holland Park for the University of London, and to report fully to the Council thereon. By the standing orders of the Council no speeches are allowed on motions involving references to committees, and this motion, was accordingly passed without any discussion; the discussion will be forthcoming when the Education Committee reports. Captain Swinton, with the consent of the Council, withdrew a part of his motion which included reference to the availability at Holland Park of a site of ample size and convenient situation, and purchasable at a capital cost considerably less than that of the far smaller site at Bloomsbury.

off some Latin verse may well have been a fashionable and cultured pastime. Thus, in the course of his biographical essay on Elisha Bartlett, the late Sir William Osler writes: "It is remarkable how many physicians write poetry or what passes as such. I have been told of a period in the history of the Royal College of Physicians of London when every elect (censor), as they were called, had written verses." Book-collecting is a hobby not unknown among medical men, and Dr. Dana's example may stimulate some of us to specialize in the poetical works of our colleagues.

It is, indeed, interesting to consider for a moment what kind of poetry mainly appeals to members of our profession in their hours of ease. In attempting to answer this question appeal may be made to *A Physician's Anthology of English and American Poetry*, selected and arranged under eighteen headings by Drs. Casey A. Wood and Fielding H. Garrison.² This collection is devoted neither to poetry by medical men, though they are not excluded, nor to poems on medical subjects. It has been made on the basis of Goethe's view that the only inspired poem is the short occasional one, struck out in a momentary clairvoyance; accordingly, the longer and sustained flights of inspiration, as in Milton and Wordsworth, are not included. In his scholarly foreword Dr. Fielding Garrison points out that from the beginnings of civilization medical men have excelled in serious studies, and that in the generation just past the poets most favoured by them were those who dealt with the ethical and philosophical aspects of life, such as Wordsworth, Shelley, Matthew Arnold, Clough, Lord Houghton, and Emerson; whereas Arnold's poetry seldom appeals to the average successful man. The explanation put forward is that a good doctor's adjustment to life—cheerful, humorous, and friendly in external relations, but austere in the background of his mind—is very like Arnold's own account of the poet's muse. By his calling and contact with disease the doctor naturally tends to become a realist; and escape from the ugliness of life, which reached its climax in the great war, may be afforded him by the finer strains of British poetry. The selections in this anthology begin with those dealing with "Youth and Manhood," and the last three headings are entitled "Tedium Vitae," "De Senectute," and "Divina Mors"; they have kept clear of the hackneyed verses that so commonly appear in anthologies, and are drawn from over a hundred authors, those most in evidence being Arnold, Emerson, Lecky, Tennyson, and Wordsworth. In the section "In War Time" Rupert Brooke's "The Dead" rightly finds a place, but we miss his fine lines on "The Soldier" and also John McCrae's "In Flanders Fields."

This anthology was originally intended as a tribute to the late Sir William Osler on his seventieth birthday, but, although the contents had been approved by him, the volume was not out of the publisher's hands at the time of the death of this beloved physician. Dr. Fielding Garrison has therefore added to his foreword a finely expressed appreciation of "the great liaison-officer of the Anglo-Saxon profession," whose combination of spiritual gravity with attractive humanity amounted to a kind of genius. Though he never wrote verse, Osler by his written and spoken word stimulated his pupils "to recognize the true poetry of life—the poetry of the commonplace, of the ordinary man, of the plain toil-worn woman, with their loves and their joys, their sorrows and their

griefs"; and to him as the great humanist of modern medicine, the friend, inspirer, and encourager of youth, this anthology has been affectionately dedicated.

AN OUTBREAK OF LETHARGIC ENCEPHALITIS.

THE number of cases of lethargic encephalitis is increasing in England, and perhaps particularly in London. During November only 4 cases were notified in London; in December 6 or 7 cases were notified in each of the later weeks, and in the weeks ending January 8th and 15th the numbers were 13 and 14 respectively. In the week ending January 22nd, 21 cases were notified, in the following week 29, and in the week ending February 5th, 22. At the same time cases have been reported from various parts of the country—the Isle of Wight, Dorset, Derbyshire, Staffordshire, and Northumberland. A case is reported also from the North of Ireland (co. Armagh). The cases in Staffordshire occurred in the Potteries; four patients there have been under treatment in the isolation hospital, of whom one has died, and several other patients are being treated in their own homes. The two cases in Dorsetshire were from villages widely apart, and it is commonly difficult to trace the source of infection. Nevertheless, in a collection of cases made for the Ministry of Health multiple cases of three and two in the same house were noted, and Dr. A. Salusbury MacNalty¹ has recently presented a report on a remarkable outbreak in August, 1919, at the Rescue and Training Home at Derby. It appears that this explosive outbreak attacked 12 out of 22 female residents, 2 cases arising on August 2nd, 8 in the next three days, and the remaining 2 on August 19th and 27th. In a previous collection of cases made for the Ministry of Health multiple cases of 3 and 2 in the same house were noted, but there is no record of an outbreak such as that at Derby. Nine of the 12 cases, all comparatively young, belonged to the type with general symptoms and ophthalmoplegia, which contains 75 per cent. of the total cases of the disease; 5 of these 9 cases, including the first one, proved fatal, and were exceptionally rapid, with a duration of three to ten days, whereas in the author's previous collection the average duration of the fatal cases was three weeks. From the acuteness and number of the cases it would appear that the virus was highly virulent, and that there was a departure from the usual sporadic to an epidemic form of the disease; it is also possible that the severity of the outbreak was partly due to the youth of these nine patients. The remaining 3 cases were "abortive," and occurred in women aged 40, 34, and 30 years. The source of the outbreak could not be traced, though the presence of an unrecognized "abortive" case or carrier cannot be excluded; no case of encephalitis lethargica, of acute poliomyelitis, or of a similar obscure illness had been recently notified in Derby. The clinical symptoms of the cases corresponded closely with those of encephalitis lethargica, and differed from those described in botulism, and there was no reason to suspect poisoning by belladonna, stramonium, hyoscyamus, or solanum. The pathological report is of particular interest, for microscopic examination of the brain in four of the fatal cases—two by Professors H. M. Turnbull and J. MacIntosh and two by Drs. Da Fano and Helen Ingleby—did not show the lesions characteristic of encephalitis lethargica. But any doubt as to the correctness of the clinical diagnosis are dispelled by Professor MacIntosh's production of a fatal lethargic illness in a monkey by means of intracerebral and intraperitoneal injection of a filtered emulsion of cerebral tissue from the first case, the monkey's brain being found by Professor Turnbull to show the characteristic histological changes of encephalitis lethargica in man. This appears to be the first indisputable occasion upon

² *A Physician's Anthology of English and American Poetry*. Selected by Casey A. Wood and Fielding H. Garrison, M.D. New York, London, New

¹ A. Salusbury MacNalty: Appendix vii to the Chief Medical Officer's Report, 1919-1920.

which experimental transmission of encephalitis lethargica to an animal has been successful. The probable explanation of the negative results of examination of the brains of the fatal cases is that the course of the disease was so rapid that there was not time for the characteristic inflammatory changes to appear in the central nervous system.

DISPOSAL OF SURPLUS MEDICAL STORES TO HOSPITALS.

SIR NAPIER BURNETT, on behalf of the Joint Council of the Order of St. John of Jerusalem and the British Red Cross Society, has concluded an arrangement with the Ministry of Munitions for the disposal on favourable terms to hospitals and convalescent homes, and similar institutions supported by voluntary contributions, of the great surplus of medical stores and equipment which have been left over from the war. The part played by the two societies in the transactions will be entirely a voluntary one, and, while the hospitals will have the benefit of the organization and the low prices, the whole of the proceeds will go into the national exchequer. At the present time the stores have been offered for sale along with other surplus goods by the Ministry of Munitions in the usual way, but as the medical stores are mixed up with other goods in the dépôts scattered throughout the country it has been difficult for hospitals and others interested to view them and to obtain them in a satisfactory manner. By the new arrangement the medical stores and accessories have been separated, and they will all be brought to one central dépôt at Shepherd's Bush, London, W. At this dépôt the goods can be inspected by hospital officials, and sales will be effected through the officials of the two societies. The stores that are available for disposal include such medical stores as surgical and dental instruments, x-ray apparatus, drugs, and surgical dressings. Samples will be on view from stores that are included in other departments—such articles, for instance, as hospital beds, furniture, clothing, bedding, ward equipment, trolleys, lockers, and tables. The articles for disposal are all being carefully examined and graded so that the purchasers can be assured that every article which is purchased is fit for use, as goods that are not in a serviceable condition will not be allowed to be included in the sale. The first grade will consist of those stores which are in an absolutely new and first class condition, and the second grade of stores will be those partly used, soiled, or chipped. It is expected that the goods will be ready for sale early in March, and as soon as the work of collecting and grading has been finished, a circular will be sent out to every hospital and similar institution in Britain describing the stores that will be on sale and the time when they will be on view. Each hospital will receive a special card of admission for the inspection of the stores at the dépôt. During the war many hospitals have had of necessity to allow their equipment to run down both in quality and quantity, and this sale of surplus medical stores affords them an excellent opportunity of replenishing it. Although the Ministry of Munitions has invariably carried on its sales on a cash basis, Sir Napier Burnett has been able to have the concession allowed to hospitals of obtaining three months' credit in regard to these purchases. The quantity of material available is very large, as it is estimated that there are £500,000 worth of surplus medical stores in this country alone, while large supplies are still expected from overseas. Hospitals are requested not to make any immediate effort to view or to purchase these goods, as they are not yet ready for inspection, and they will be informed of the actual date when the dépôt will be open. If, however, any hospital authorities eligible for participation in this scheme do not receive a circular by the end of this month, they are requested to communicate with Sir Napier Burnett at the offices of the British Red Cross Society, 19, Berkeley Street, London, W.1.

THE LONDON UNIVERSITY PHYSIOLOGICAL LABORATORY.

THE fate of the Physiological Laboratory of the University of London still hangs in the balance. As was stated a fortnight ago, the Physiological Society has unanimously expressed the opinion that the closure of the laboratory would be a grave injury to the advancement of science and knowledge and to the teaching of physiology in London, and would therefore be contrary to the public interest. We learn from an article by the Director, in *Education*, that the matter will come before the Faculty of Science of the University at its meeting on March 4th. A little over ten years ago the Senate, after receiving identical reports from the academic and internal councils to the effect that "it is highly desirable that the work of the Physiological Laboratory be continued as forming a valuable part of the work of the university," resolved to allocate £800 towards the maintenance of the laboratory. Last December the Senate, because it wishes to use the rooms now occupied by the Physiological Laboratory for its expanding clerical staff, and because the London County Council has suspended its annual grant of £500 a year for the laboratory, resolved that the laboratory should be closed at the end of July next unless the London County Council at once restored its grant. This, we fear, the Council is not likely to do, and unless public scientific and medical opinion can influence the Senate the valuable work which has been carried on unremittably by the laboratory since it was opened by the Chancellor in 1902, will be brought to an end. Looking back to the last annual report of the Physiological Laboratory Committee, signed by Sir David Ferrier, we find that a great deal of important work was in progress during 1919. In pursuance of the policy proper to a university laboratory of teaching the teacher, courses of advanced lectures are given annually, and last year the Director gave two courses, one on the energy balance of the human body and the other on electric signs of emotive activity. During 1920 the Director pursued his researches on these subjects, and Mr. J. A. Gardner, reader in physiological chemistry in the University, with his assistants, was able to resume lines of research with the prosecution of which the war had seriously interfered; those now in progress are concerned with the digestibility of fats, and in particular with cholesterol metabolism in disease and in infants under various diets. Among other researches undertaken was that by Dr. Burridge on the action of salts, a subject which has a pharmacological bearing, and by Dr. Ellis, the recently appointed lecturer on chemistry at St. Mary's Hospital, on fats. Farther, a working anaesthetist has been engaged under the supervision of the Director in the quantitative estimation of chloroform. During last year there were altogether ten workers in the laboratory. We hope, therefore, that in all the circumstances the Senate will reconsider its recent decision and revert to the policy affirmed by it in 1910 and by the Vice-Chancellor, Dr. Robertson, at an earlier date, when he said: "I think the University is too deeply committed to the success of the (Physiological) Department to permit its abandonment except at the cost of a very serious confession of failure, the effect of which on the position of the University would be most injurious."

PUBLIC HEALTH IN CZECHO-SLOVAKIA.

A MEDICAL commission appointed by the Government of Czecho Slovakia is at present in this country to study public health institutions and administration. On February 14th the commission visited the Central Meat Market and the Fish Market, and were afterwards entertained at luncheon in the Guildhall by Alderman Sir Charles Wakefield, who spoke warmly of the hospitable reception accorded to a civic deputation to the Czecho Slovak Festival of Freedom last year in Prague. He expressed the hope that, under the direction of Sir George Newman,

the commission had already seen much that interested it, adding that the members of the Sanitary Committee of the City Corporation and Dr. Howarth, medical officer of health, would be anxious to show it the methods adopted for dealing with food control. The London meat market, Sir Charles Wakefield said, is the largest for dead meat in the world, receiving enormous quantities of imported, home killed, and tinned meats, and provisions of all kinds, including green vegetables from the Continent. To regulate, with due regard to the public health, the distribution of these great quantities of food, a huge machinery had grown up and was working with great efficiency. Czecho-Slovakia had recognized that efficient public health administration was one of the tests of a country's civilization. The war had left an evil legacy of special difficulties to Czecho-Slovakia, but that enterprising new country was tackling the problems of public health with characteristic energy. Dr. Halek, speaking on behalf of the Czecho-Slovak Ministry of Health, said that the Commission had found its short study of English public health institutions very encouraging. English civil sanitary administration, like her military sanitation, was unrivalled, and her voluntary hospitals, like her devoted nursing service, were models for others to follow. Sir Charles Wakefield proposed the health of President Masaryk, President of the Czecho-Slovak Republic; the toast was acknowledged by Dr. Mastny, Czecho-Slovakian Minister in this country. Sir George Clerk, British Minister in Prague, spoke in sanguine terms of the future of the Czecho-Slovak Republic. The Commission, which consists of Dr. Vladimir Bazika, Dr. Bohumil Vacek, Dr. Ivan Halek, Mr. Antonin Kolinsky, Dr. Vladimir Petrik, and Dr. Karel Driml, has recently paid a visit to the United States and will spend some time in France on its way home.

EFFICIENCY ON VIEW.

THE average man, conscious of his failure to reach 100 per cent., comes away more depressed than ever from the Efficiency Exhibition now being held in London. Under the roof of Olympia have been gathered mechanical substitutes for most of his mental processes, certainly including those of memory, calculation, and sustained attention, as well as for his physical strength and skill. Here he finds machines which are ready to act as his accountant, his private secretary, his housekeeper, his porter, and also as his candid friend and mentor, checking every motion he makes and almost every breath he draws. At the same time, the detached observer may wonder whether all this brisk efficiency, all this frictionless movement, which eliminates error and reduces the time factor to the minimum, is quite the ideal after which to strive; a little margin of frailty may be Nature's intention for us. It is therefore in certain individual exhibits rather than in general impressions that the leisurely as distinct from the commercial mind will find interest. The University of London illustrates its teaching and research work; Middlesex Hospital the daily routine of its research department, and St. Mary's Medical School the uses of industrial medicine—this last in enforcement of an appeal which is being made for the establishment of a department in that subject at a cost of £60,000. The visitor is also afforded a glimpse of the Metallurgical Department at Sheffield University, and of Armstrong College, Newcastle, where there is an apparatus for determining the liability to explosion of various coal dusts and the inhibitory power of inert dust. Electricity has always stood at the right hand of efficiency, and many of its newer uses are demonstrated at the stand of the British Thomson-Houston Company, where there is also a Coolidge portable x-ray outfit comprising everything necessary for x-ray examination by the bedside. The apparatus can be brought to the house in the doctor's motor-car, carried upstairs, and worked from the nearest lampholder or wall plug. The visitor's eye will

be caught by many other devices, from an improved system of sewage purification to a scheme for artificial daylight, and from the latest form of hygiene propaganda to the construction of ophthalmic lenses. The exhibition remains open until February 26th.

MEDICAL INSTITUTE FOR NEWCASTLE.

IN presenting a Medical Institute to the medical profession in the North of England, Dr. J. W. Smith, of Ryton-on-Tyne, has provided a much-needed want and has raised a memorial—in a form more valuable and holding more promise of keeping green the memory than most memorials—to his son, Dr. J. Wilkie Smith, a young doctor of medicine of great promise who died six years ago. Dr. J. W. Smith, who is an ex-president of the North of England Branch of the British Medical Association and of several other medical societies, is one of the best-known men and represents the finest type of general practitioner of the North; he has shown vision beyond the ordinary in the gift of this medical club. Property was secured at 7, Windsor Terrace, Newcastle-on-Tyne, and alterations were made so as to provide suitable accommodation for a dining-room, lounge, card and billiard rooms, in addition to a library, lecture and committee rooms and bedrooms for country members. The building has been redecorated throughout and the rooms have been tastefully furnished; thus the Institute has an attractive and home-like air, appropriate to its object. On February 10th a large gathering of medical men took place at the Institute, when the presentation of it to the trustees was made by Dr. J. W. Smith. In making the presentation Dr. Smith said that he hoped it would provide not only a social and scientific centre for the profession in the North, but also that the members would not forget the cognate sciences; and he especially remarked on the value of philosophy, literature, and music to medical men in their mission in life. The gift was received by Professor Rutherford Morison on behalf of the trustees; and Professor Drummond, who presided, thanked Dr. Smith in a feeling speech for his munificent and timely gift. Those present were afterwards entertained to tea, and it was agreed that, although the Institute was now open, there should be an official ceremony at an early date to celebrate the event. Intending members should make application to the honorary secretary, Dr. Stanley Robson, at the Institute.

AN AMERICAN FIELD MARSHAL.

THE title of "field marshal of American surgery" was applied by Dr. de Schweinitz to Dr. William Williams Keen on January 20th; the occasion was the celebration of Dr. Keen's 84th birthday, when he was entertained at a banquet in Philadelphia, was presented with a life-size bronze portrait bust, and listened to speeches and poems in his honour. Dr. Keen served as a surgeon during the Civil War in America, and during the great European war; though on the later occasion he did not leave his own country, he did much important work and was gazetted lieutenant-colonel; in the bust he is shown in the uniform of that rank. In the interval between the two wars Dr. Keen attained a commanding position as a surgeon, a teacher, and a writer. His books on the surgery of the brain and of the spine first made his name widely known, and it became a household word in this country after the publication of the great *American Textbook of Surgery*, which he edited in co-operation with the late Dr. William White. During the war he produced a small handbook on the *Treatment of War Wounds*, which ran through several editions. The banquet on January 20th was an assembly remarkable in numbers—for over 600 men and 200 ladies were present—and in the representative character of the attendance. The speakers included the president of the Brown University, where

Dr. Keen graduated in 1859, who said that the outstanding traits in Dr. Keen's character were "a wholesome discontent and a persistent optimism." Dr. William Welch, of Johns Hopkins University, spoke of Dr. Keen's powers as a teacher, and of his great services as a defender of methods of research in medical science. He had earned the gratitude not only of this but of all future generations by successfully combating ignorance, prejudice, and unscrupulousness. We may recall that Dr. Keen embodied his views in a volume entitled *Medical Research and Human Welfare*. Dr. J. C. Da Costa, Dr. Keen's successor as professor of surgery in Jefferson Medical College, gave a short account of Dr. Keen's life. After recalling that when Dr. Keen was born the population of the United States was only 16,000,000 and that of Philadelphia 170,000, while there were only 120 miles of railroad in America, he said that Dr. Keen was foremost among those who changed the crude surgery of the middle of the nineteenth century to the surgery of to-day, and his character was such that his assistants and colleagues at Jefferson Hospital "were his adherents, sworn, true and faithful as soldiers of Napoleon." Mr. D. J. Hill, formerly Ambassador to Germany, and Dr. Keen's friend for five-and-thirty years, eulogized him as a man the whole nation honoured, not only as a surgeon and as a man, but as a servant of his country. Four volumes, containing over 800 letters and telegrams of congratulation from friends, were then presented to Dr. Keen by General Merritt W. Ireland, Surgeon-General of the United States Army. The presentation of the bust was made by Dr. William J. Taylor, President of the College of Physicians of Philadelphia. Dr. Keen, in his reply, said that his professional life covered sixty-one years, forty of which were spent in service as a teacher, a service of which no one not himself a teacher could imagine the joy. If asked the secret of his long life he would reply, "Have some unfinished but not too urgent task awaiting you right outside the door, and you can murder time in the first degree."

FILARIASIS EXPEDITION.

THE London School of Tropical Medicine has arranged to send an expedition to British Guiana to investigate filariasis with the view of obtaining information as to its prevention and treatment. The expedition is being sent at the request, made shortly before he left the Colonial Office, of Lord Milner, who considered that the Government required further advice as to the best method of controlling the disease. At the suggestion of Sir Patrick Manson the expedition will visit also certain West Indian islands, choosing one, such as Barbados, where the rate of attack is high, and another, such as Grenada, where it is low. It is hoped that by comparing and contrasting the circumstances of two such islands light may be thrown on the conditions which favour filaria. The leader of the expedition is Professor R. T. Leiper, director of the helminthology department of the London School of Tropical Medicine; the other members are Dr. G. M. Vevers, demonstrator of helminthology in the School, Dr. John Anderson, Dr. Chung Un Lee, and Dr. Mahommed Khalil of the Egyptian Medical Service. The expedition will sail early next month.

MEASUREMENT OF HUMAN EMOTION.

THE discourse at the Royal Institution on February 4th by Dr. A. D. Waller, F.R.S., the Director of the Physiological Laboratory of the University of London, was concerned with the galvanometric measurement of manifestations of emotion in man. Physiologically all emotions, he pointed out, are expressed as neural outbursts from the central nervous system through efferent nerves to muscles and glands. The manifestations in general were due to intensified physiological activity at the periphery, such as a blush, pallor, a rush of tears, or a dilated pupil. The physical sign of emotion known, since the observations of

Veraguth of Zurich in 1909, as the psycho-galvanic reflex, afforded the most convenient gauge of human temperament, since it declared how much a given subject was moved by his thoughts and feelings. The emotive response was in the main a phenomenon observed in the palm, though it occurred also in the sole. If the hand and the forearm of an ordinary individual were connected with each of two galvanometers and two Wheatstone bridges, the reaction of the arm was steady, while that of the hand was irregular. To a sudden pin-prick, threatened or real, it gave a smart and obvious response. The magnitude of the response in either case varied with different people; in those who might be called "positives" little or no disturbance was caused by the threat, but in those whom he termed "imaginatives" or "sensitives" a large response occurred to the threat, larger, it might be, than to the real pin-prick. The "imaginatives" might be further distinguished into different classes; high in the scale were persons who could at will either keep quiet, or think thoughts, or see imaginary visions or hear imaginary words. To watch the galvanometric signs of these subjective phenomena was very interesting both to the onlooker and to the subject, especially the latter, to whom to sit quietly watching himself think became an absorbing pastime. The emotive response varied in different individuals and in the same individual with different states of mind and body. The distribution of the response over the body was especially interesting. In normal persons it was confined to the palms of the hands and the soles of the feet, but in "sensitives" it extended up the limbs. The few spiritualistic mediums Dr. Waller had been able to examine had, with one exception, given the reaction proper to "sensitives." Diurnal variations of the reaction occurred, the responses being best about the middle of the day, when physiological activity was high. The question had been asked whether pleasant and painful sensations produced similar or opposed galvanometric deflections. The emotive response was a sharp movement and occurred always in one direction—decreased resistance—that is to say, increased permeability. Increased resistance was never observed, but only sometimes diminished permeability. Dr. Waller went on to make a further classification of individuals into (1) "sensitives" or "imaginatives"; (2) "normal," including the majority of men and women; (3) "insensitives," in whom were included hysterical subjects (pythics); and (4) certain other cases that might be called "super-sensitives"; some shell-shock cases were included in both the third and fourth categories. In concluding his lecture, Dr. Waller said that these cases required further investigation, and that, in fact, no general conclusions could justifiably be drawn from the facts he had put forward until more data had been collected.

THE NEW PARLIAMENTARY SESSION.

OUR Lobby Correspondent writes: But for the fact that the legislative programme of the Government was already to a large extent known, the outline contained in the Speech of the King, on opening Parliament on February 15th, would have been disappointing. No reference whatever was made to health matters, except in so far as a bill to deal with liquor trade administration may be deemed to come within this category. The fact that there is no mention of any measure for the reform of the Poor Law must, it is to be feared, be taken as evidence that none will be introduced this year. On the other hand, the omission of any allusion to the Patent Medicines Bill, the Dentists Bill and to certain important provisions in the Ministry of Health (Miscellaneous Provisions) Bill need not cause serious disquietude if the medical group in the House of Commons do their duty in drawing attention to the urgency of these considerations. The Government having gone so far in these affairs, explicit remark upon them was hardly to be looked for in the Speech from the Throne. Nevertheless, it

would have been reassuring as to the Cabinet's earnestness in this connexion if some comprehensive observation covering this field had been included in the deliverance, since the King speaks on the advice of his Ministers. In the prospect of a shortened and crowded session, some pressure of parliamentary and public opinion may be desirable in order that the measures indicated may get a fair place in the time-table after the financial business—which must have priority—has been dealt with.

EYE-STRAIN IN CINEMATOGRAPH HALLS.

THE London County Council, as briefly stated at the close of an article on the cinematograph in our last issue (p. 234), has adopted the recommendations of the committee appointed by the Illuminating Engineering Society to inquire into eye-strain in cinematograph halls. These recommendations will be put into force at once so far as new halls are concerned, and will be applied to existing halls as opportunity offers. The chief recommendation sets out the limit of the vertical angle of view. The committee believes that ocular discomfort arises mainly from the abnormal angle at which very often the eyes of spectators are directed upwards, and that conditions suitable for the eyes would be secured if a moderate value for the angle of elevation were adopted. It is therefore proposed that the angle of elevation subtended at the eye of any person seated in the front row by the length of the vertical line dropped from the centre of the top edge of the picture to the horizontal plane passing through the observer's eye shall not exceed 35 degrees. In some of the London halls this condition is complied with, and in others it is approached, but in others again the angle in question exceeds 60 degrees.

The summer meeting of the Section of Laryngology of the Royal Society of Medicine will be held on Thursday, June 2nd, Friday, June 3rd, and, if necessary, will be extended to Saturday, June 4th. In addition to the reading of papers, there will be demonstrations on various subjects, an exhibition of instruments, and a museum.

MEMORIAL TO SIR VICTOR HORSLEY.

We published on January 1st a circular letter issued by the general committee formed to establish a memorial to the late Sir Victor Horsley. The intention is, if sufficient support is obtained to found a lectureship in the University of London by which Sir Victor Horsley's name would be perpetuated.

The first list of subscriptions amounted to £324 17s.; since then the following additional subscriptions have been received:

SECOND LIST OF SUBSCRIPTIONS.

£100—Mr. and Mrs. Edward Robinson.
£20—Sir F. W. Chance.
£10 10s.—Mrs. W. S. Coleman, A. H. Burgess, C. H. Carlisle.
£10—Miss M. W. Ranken.
£5 5s.—Sir Berkeley Moynihan, F.C.M.G., C.B., Sir A. Pearce Gould, F.R.C.S., C.B.E., J. Smith Whitaker, F. J. Hopkinson, Wilfred Trotter, Miss Mary Robin-on, Miss Margaret Knowles.
£5—Mrs. Scharlieb, C.B.E., M.D., Mrs. Rosa Napier, Miss Emily Chaplin.
£3 3s.—Sir Thomas Barlow, Bt., F.R.C.S., Sir Humphry D. Rolleston, K.C.B., Harry Platt, M.S., Dr. Thomas Wilson, Mrs. Frances Levy, Dr. Thomas W. Thomas, Dr. W. H. Rivers, Anonymous (per Dr. Collier).
£2 2s.—Sir William Macdonald, C.B., Dr. E. Rowland Totherill, Night Rev. Dr. Hine, Dr. May Thorne, Sir S. Squire Sprague, Mrs. Henry Fawcett, J. H. Morgan, F.R.C.S., Dr. George Pernet, Emeritus Professor James Sully, Dr. J. A. Macdonald, Dr. Edwin Bramwell, Mr. Professor de Webbe and Lord Mrs. E. J. Chick.

In the previous list, p. 19, the name of Sir Cecil Harrison, K.B.E., was incorrectly given.

Subscriptions made payable to "the Victor Horsley Memorial Fund" may be sent to the Honorary Treasurers, Sir Frederick Mott, K.B.E., Maudsley Neurological Hospital, Denmark Hill, S.E.5, and Dr. Howard Tooth, C.B., F.R.C.S., 34, Harley Street, or the Honorary Secretaries, Sir W. Arbuthnot Lane, Bt., C.B., 21, Cavendish Square, W.1, and Edward J. Domville, C.B.E., Shutes Symonds-bury, Bridport.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

THE HUNTERIAN FESTIVAL DINNER.

THE Hunterian Festival Dinner of the Royal College of Surgeons of England was held on February 14th—the anniversary of John Hunter's birth—in the library of the College, with the President, Sir ANTHONY BOWLEY, in the chair. H.R.H. the Prince of Wales honoured the College with his presence, and during the evening was formally admitted an Honorary Fellow, and signed the Roll. The Prince was received by the President, the Vice-Presidents, Sir Charles Ballance and Sir John Bland-Sutton, and the Secretary, Mr. S. Forrest Cowell. Four past Presidents of the College—Sir John Tweedy, Sir Henry Morris, Sir Rickman Godlee, and Sir George Makins—were presented. The company, which numbered nearly 100, included the Speaker of the House of Commons, the Marquis of Salisbury, Viscount Hambleden, Lord Lamington, General Lord Horne, the High Commissioners for Canada and New Zealand, the President of the Royal Society, the Presidents of the Royal College of Physicians of London and the Royal College of Surgeons of Edinburgh, the Lord Mayor and Sheriffs of London, the Dean of Westminster, the Treasurers of Gray's Inn and the Inner Temple, the Masters of the Society of Apothecaries and seven other City Companies, the medical heads of the Navy and Army, and Professor Theodore Tuffier of Paris.

The President's Speech.

Sir ANTHONY BOWLEY, in proposing the health of the Prince of Wales, said:

May it please your Royal Highness,—The Royal College of Surgeons of England is the descendant of two civic institutions which date back to the fourteenth century—namely, the Guild of Surgeons and the Company of Barber Surgeons, but it was founded by Charter as a Royal College in the year 1800. It was not, however, until the College celebrated its centenary in 1900 that it became empowered to create Honorary Fellows, and its first Honorary Fellow, Sir, was your illustrious grandfather, King Edward VII, who, while Prince of Wales, was graciously pleased to accept our Diploma in June, 1900. At a later date King George bestowed upon us a similar distinction, and I have now the honour of welcoming your Royal Highness as the third Prince of Wales to become an Honorary Fellow of the College.

Since the election of its first Honorary Fellow the College has from time to time elected other Fellows, and has generally done so in order to commemorate some important event. Following this precedent, it proceeded on July 24th, 1919, to commemorate the close of the Great War by electing six Honorary Fellows from those who had specially distinguished themselves in the war, and it was under these circumstances, Sir, that we requested you to allow us to propose your name. We knew the encouragement that your presence has been at the front; we appreciated your zeal and keenness for everything that benefited our soldiers, and, above all, we admired the spirit in which you performed the duties allotted to you as an officer in His Majesty's army. On the same date we elected His Royal Highness the Duke of Connaught, not only as a representative of the Royal House who had been closely associated with the army all his life, but also because he was the Colonel-in-Chief of that Royal Army Medical Corps which had served with such great distinction, and won for itself such universal praise. We elected Dr. Pierre Duval, the distinguished French surgeon, and Dr. Depage, the equally eminent Belgian professor, both of whom had so closely co-operated with us in the field, and had personally attended many British soldiers. Finally, we elected two representatives of our sister nation, the United States of America, and we chose Brigadier-General Finney, the "Chief Surgeon" to the American army in France, and the Professor of Surgery at Baltimore, and Charles Mayo of Rochester, who had acted as adviser to the Army Medical Service in America, and whose fame is world-wide. The medical professions of Great Britain and of the United States have for many years enjoyed the closest co-operation and friendship, and we were in no way surprised that, as soon as ever the drums of war beat to arms, the surgeons of America sprang to our aid. Within a very few months they supplied the personnel of six general hospitals, and, at a later period, over one thousand of them served in our army in France pending the arrival of their own troops. They served in our base hospitals, in our regiments, our field ambulances, and our casualty clearing stations during the third battle

of Ypres, and amongst them we were especially glad to welcome some of our own Honorary Fellows.

Such, Sir, is a brief record of the claims of the Honorary Fellows elected as representatives of our Allies at the time when you consented to accept our Diploma, and the College has never been more fortunate than in the distinguished names which it has been able to add to its roll at the end of the Great War.

The Royal College of Surgeons performs various public duties which I will not detail. It is the national custodian of the unequalled Hunterian Museum. It possesses a most valuable library open to the whole medical profession, and the Members and Fellows who have passed its examinations number, at the present time, nearly 18,000. Our great master, John Hunter, was the Surgeon-General to the army for some years before his death in 1793, and ever since his time large numbers of men holding our diplomas have served with the imperial forces of the Crown. The present chief medical officers of the Navy, of the Army, and of the Air Force, are all Members of our College, and several thousand of our Fellows and Members served in the late war. Over 350 of these gave their lives for their country, and your Royal Highness knows from your own experience in France that these lives were not given in vain.

We, Sir, in common with all sections of the community, have watched with the deepest interest both the career of your Royal Highness in the war, and also your more recent and invaluable missions to those great British possessions overseas which have so gallantly supported our common cause. We recognize that, both in war and in peace, in France and in the Dominions, you have been a fertile source of inspiration and of good fellowship, and, at the same time, we like to recall that, however far you may have roamed, you have not visited a Dominion or a Colony in which our College was not represented. We may indeed justly claim that, while the heart of our College is in England, our Fellows and Members circulate throughout the world. You, Sir, have been frequently described as "Britain's best Ambassador," but, if I may say so, you are far more than that. An ambassador is but the delegate of a friendly country to a foreign nation, while you are a living and indispensable link in that human chain of common aspirations, common ideals, and common patriotism which binds together all parts of our great Empire in a bond which is infinitely more enduring and unbreakable than all the treaties that ever have been or ever will be written. We use no mere form of words when we say that we fervently trust you may long live in health and happiness to further the good work for the Empire you have so successfully begun. In the name of the Royal College of Surgeons of England, Sir, I beg to thank you most heartily for coming amongst us this evening, and for doing us the honour of becoming an Honorary Fellow.

The Prince of Wales's Reply.

After the Prince had received the diploma and signed the roll of Honorary Fellows of the College, he said:

I thank you very much for bestowing on me, as you did on my father and my grandfather, the Honorary Fellowship of the Royal College of Surgeons of England. I am proud that I should have been elected at the same time as my uncle the Duke of Connaught and four of our distinguished Allies. The College of Surgeons has done splendid work for well over a century. Before the war I think that but few of my contemporaries knew all that the letters F.R.C.S. meant, but the war brought home not only to them but to everybody the full significance and meaning of these letters, and all the long years of successful research and experiment they stand for. Before we went out to the front—I am speaking of my contemporaries—we began to take a practical interest in surgery. Regimental doctors or the doctors of whatever units we were attached to lectured to us. Our female relatives and friends ministered to us and often practised on us, and later on all those who got in the way of a Hun bullet or shell became passive subjects of surgical work. All who served in the war had great or small dealings with your profession and its members, and I have heard nothing but the deepest gratitude expressed towards the medical branches of both Services and those who belong to them, from the surgeons—those who had regular commissions, and thousands (many of them members of this College) who joined up—down to the sick-beth stewards and, in the case of the Army, the orderlies. I include here those eminent surgeons like our chairman, who gave their valuable time, their help, and their advice. Among the

most gallant episodes of the war were those of the unarmed battalion medical officers and their small staffs of stretcher-bearers. The work done by our surgeons and our doctors forms one of the finest chapters in the history of the war. There is no doubt that the fact that the men knew that if they were wounded they were going to be well treated cheered them more than we can understand. It is in this building that so much of the work and the knowledge which made all this possible had its origin. Knowing what that work was, having seen something of it myself, and realizing what is being done here, makes me doubly proud of the honour which has been done me to-night by your having admitted me to your Fellowship.

After the toast of "The Memory of John Hunter" had been honoured standing and in silence, the health of the many distinguished guests who were present to do honour to the science and art of surgery was proposed by Sir Charles Ballance. This toast was replied to by the Speaker of the House of Commons, who praised the good work done by the ten medical members in the present Parliament—"a modern baker's dozen." The health of the Hunterian Orator was proposed in an admirable speech by Sir George Parkin, Administrator of the Rhodes Bequest, who spoke from forty-five years' acquaintance with his fellow Canadian, Sir Charles Symonds, and impressed upon his hearers the importance of the reflex movement of students to Britain from the Dominions.

Scotland.

ASSOCIATION OF SCHOOL MEDICAL OFFICERS OF SCOTLAND.

A CONFERENCE has been arranged by the Association of School Medical Officers of Scotland, to be held on April 7th, 8th, and 9th, in the Provincial Training College, Edinburgh. On the first day a series of lectures will be given: Dr. Shrubbsall, medical officer to the London County Council, will lecture on "Mental Deficiency," Dr. Norman Walker on "Skin Diseases in Schools," and Dr. MacGillivray, oculist to Dundee Educational Authority, on "The Educationally Blind Child," followed by a demonstration of the methods of education of such children. On the second day of the conference, through the co-operation of the Scottish Board of Health with the association, Professor Dreyer, M.D., of Oxford, will lecture on his recent work on "The Assessment of Physical Fitness," followed by a demonstration of apparatus and methods. This lecture, besides being of interest to medical practitioners engaged in school health work, should also attract medical officers of life insurance companies, and those companies which have offices in Edinburgh are being invited, therefore, to send their medical officers, and other officials interested, to this lecture. In the afternoon of the same day a joint meeting will be held with the Scottish League of Organizers and Teachers of Physical Training to discuss physical education, followed by a demonstration arranged by the Scottish League. On the third day of the conference visits will be paid to special schools and other institutions of interest in Edinburgh. The secretary of the conference is Dr. John Hunter, 8, Abercromby Place, Edinburgh, who will supply any further information which practitioners who are interested might like to have.

GLASGOW ROYAL INFIRMARY.

The report of the managers of the Glasgow Royal Infirmary for 1920 shows an improvement in the finances of the institution compared with the previous year. The managers have completed the year with a surplus of £5,903, and have been able to replace that amount to capital reserves, which were encroached upon in 1919 to the extent of £21,100 to meet the deficiency in revenue that year. This has only been accomplished by applying for revenue purposes all legacies, bequests, and large donations.

The ordinary revenue was £81,725, being an increase of £28,923 over the previous year, and the ordinary expenditure was £116,947, an increase of £18,270. In spite of the continued increase in the cost of commodities and in wages, the deficiency in ordinary revenue was reduced to

£55,221, being an improvement of £10,653. The annual subscriptions showed an increase of £5,187.

The working class contributions were increased by £14,368; this was largely due to the adoption of the method and scale recommended by the Executive Committee of the conference which met to consider how employees of public works might effectively respond to the appeal of the infirmaries and hospitals. The scheme provided for a graduated scale of weekly contributions, with a minimum of 1d. off wages under 30s. per week, 1½d. off wages from 30s. to 40s., 2d. off wages from 40s. to 60s., 3d. off wages from 60s. to 90s., 4d. off wages from 90s. to 120s., 5d. off wages from 120s. to 140s., and 6d. off wages of 140s. and over. The workers periodically allocate the amount collected at the respective works among the institutions they desire to support.

ST. ANDREWS UNIVERSITY.

Professor David Waterston, M.D., has been appointed Adviser of Studies in the Faculty of Medicine at the University of St. Andrews, in place of Professor Herring, who has resigned that post on being appointed Dean of the Faculty of Science and Adviser of Studies in that Faculty.

Correspondence.

WHAT IS A SYMPTOM?

SIR,—I am obliged to Sir James Mackenzie for kindly replying to my question. Sir James gives as a possible definition of a symptom "the reaction of the tissues to an injurious agent." But is not this rather a definition of disease? A symptom I take to be an indication of the existence of disease in the living subject, which is quite a different thing; is it not?

My difficulty is to distinguish between signs and symptoms. We are in need of some term which shall embrace in its meaning evidence, of whatever kind, by means of which the presence of disease can be made manifest during life, whether by electrical and chemical tests, x-ray apparatus, exploratory incisions, or what not.

The term "symptom" is not sufficiently comprehensive for the purpose. In view of this fact and of the ambiguity attaching to the word, why not abandon it in favour of the wholly unambiguous term "sign" (*signum*)?—I am, etc.,
London, W., Feb. 12th.
HARRY CAMPBELL.

X-RAY RADIATION AND CANCER.

SIR,—The letter of Dr. James Wilcox is a welcome contribution to this important subject, and I would like to make comment thereon so far as it refers to my letter of January 29th last. The phrase "a promise of a cure" is rather more than I intended to convey. If the word "possibility" is substituted for "promise" I shall be content. Then as to casting an aspersion on our present methods, I certainly did not mean that. These methods have done well, but the science of deep radio-therapy is a progressive one, so that what seems best to-day becomes more or less obsolete at some future time. When I first heard of the method I described it seemed to me so sound in theory as to be well worth investigation on the spot. My experience convinced me that it constitutes a real advance on our methods here, and I lost no time in submitting it to the consideration of my colleagues. I could not well cast aspersion on methods practised by myself until quite recently and not yet entirely abandoned; all the same, we must move with the times.

As for the use of these very hard tubes for therapeutic purposes, it is my considered opinion that, within reasonable limits at least, the harder the better. From the very early days of x-ray therapy I have known from practical experience that hard tubes gave better results than soft ones, but at that time and for some time afterwards I could offer no adequate reason. Even the comparatively feeble filters used at first improved matters, which improvement progressed with the increasing absorption value of the filtering material—all tending towards the production of a more homogeneous beam, more nearly akin to the

hardest gamma rays. The fact that these passed through the tissues so readily led many to suppose that they could be of but limited use, on the theory that only those rays actually absorbed had any biological action. This idea has done much to retard the development of deep therapy in this country and elsewhere. In addition to this, the limitations imposed upon us by our apparatus prevented research with tubes having a resistance above about 9 in. of air. It is probably true to state that only a limited number of radiologists fully realize the wide difference in the principles underlying radiography and radio-therapy. The present day exacting demands of radiography take account only of the primary beam of rays emanating from the anticathode. Low resistance tubes must be used to get the maximum actinism, contrast, and detail; equally important is it to minimize the influence of secondary or "stray" rays. If a hard tube is used we lose not only actinism and contrast, but detail and outline are blurred or lost through the influence of these secondary radiations. Indeed it would appear that their influence increases in more rapid proportion than the hardness of the tube. While it is probably true that the harder the primary beam the less action, *per se*, it has on the tissues it traverses, it more than makes up for this in the profuse amount of secondary radiations set up.

Thus, in radiography the primary beam is all-important; in radio-therapy the chief function of the primary beam is to set up secondary rays in the locality under treatment, such secondary radiations being the principal factor in the changes that follow.

There is evidence to prove the substantial accuracy of these statements, and once realized it is easy to see how we stand to gain by increasing the hardness of our tubes. How far it is possible to go in this direction has yet to be ascertained.

That the filters in common use have too low an absorption value is easily demonstrated. It must be sufficient to make the resultant beam homogeneous; if it falls short of this the disparity between the maximum skin dose and that delivered at any given depth, such as 10 cm. below, is so great that thorough and efficient irradiation of a deeply seated lesion becomes unnecessarily difficult and prolonged. Working with a tube of high resistance (16 in.) no less than 12 mm. of Al, or 0.5 mm. of Zn, are necessary to get homogeneous rays. It is most likely that the same will be required with softer tubes, and such radiation as succeeds in getting through will be small in amount and have a very limited value.

My experience at Erlangen showed unmistakably that the use of a standard type of homogeneous radiation makes for better and more uniform results. As any practical radiologist knows, we are continually being confronted with seeming paradoxes, as instanced in the, at times, widely divergent results in more or less similar cases treated on apparently the same lines. Such are not unknown in the practice of the technique I have described, but they are rare and usually can be accounted for. The system has its defects, of course; we would like to see the time of exposure reduced, as well as the post-radiation sickness, an unpleasant though not serious immediate after-effect. I look for improvement in the use of still harder tubes, but at present it would appear that an equivalent spark gap of 16 in. is as far as it is safe to go, owing to the risk of puncture of the tube itself. If, as it seems, our late enemies have scored a point, we need not despair; let us learn the lesson gratefully and gracefully and then "go one better." British radiologists and British manufacturers may be trusted to rise to the occasion and make good.—I am, etc.,

London, W., Feb. 12th.

REGINALD MORTON.

THE PHYSIOLOGICAL LABORATORY OF THE UNIVERSITY OF LONDON.

SIR,—As a teacher of physiology in a London medical school, and as one who has worked in the physiological laboratory of the University of London, I should be grateful for the opportunity of making a few observations on the suggestion that this laboratory should be closed.

The reasons put forward for this, to my mind, retrograde step appear entirely inadequate. Although I find myself quite in accord with the view that the University should give what monetary assistance it is able to research work

February 15th.

London, W., Feb. 9th.

E. G. SEESINGER.

As to the instance mentioned some weeks since, of a

mother asking her fourteen-year-old daughter if her prophylactic armament was complete, I would quote the lines of an old hymn:

"Can a mother's tender care
Cease towards the child she bare?"

When religion, continence, and prophylaxis have overcome the awful and lasting effects of the present venereal danger, then, and not till then, should we, as a nation, exclude any and all methods tending to prevention.—I am, etc.,

Folkestone, Feb. 13th.

P. BROOME GILES.

THE NAVAL MEDICAL SERVICE.

SIR,—I am reading with much interest the correspondence to which you are kindly giving the hospitality of your columns. As a very old ex-surgeon R.N. I think it high time the Admiralty descended from their Olympus and agreed to give their consideration to a question which affects a considerable number of efficient loyal officers, and is also of much importance to the Royal Navy generally. "Surgeon Commander" is quixotic, but I fear there is likely to be a substratum of truth in what he says.

I claim to know something of the subject, having served eight and a half years in the R.N. and four years in the R.A.M.C.

Put very shortly, medical officers in the Navy—including the Director-General—have no real authority; in the Navy, quite rightly, authority and discipline mean everything. Promotion is slow and uncertain; the natural result is irritation and discontent. The commander of a ship is often years younger than the surgeon commander; the former is "Please Sir this," "Please Sir that"; the latter "The — old doc." No one can deny this; the younger officers and men are apt to take advantage of it, and a social inferiority is taken for granted.

Again, why are not naval hospitals allowed to fly the white ensign? Any ship's whaler may do so; is a naval hospital of less importance to my lords than a small rowing boat?

I have purposely not touched on the matter of pay and emoluments; let "snobishness" be officially exterminated, and everything else will automatically improve. We are no longer, as Thomas Gale wrote in the sixteenth century, "a great rabblement there that took upon them to be surgeons. Some were sow-gelders, and some horse-gelders, with tinkers and coblers." But if I were writing frivolously, the present great discontent in the Naval Medical Service does look as if there were some potential admiral-gelders about.

Seriously, the Admiralty should look into the matter; there must be quite a large number of retired, and therefore independent, witnesses to get some reliable evidence from. It is no good looking to such moribund institutions as the College of Physicians or College of Surgeons for help.—I am, etc.,

GERALD SICHEL, F.R.C.S.,

Late Surgeon R.N., Major R.A.M.C.

Sevenoaks, Feb. 12th.

A NEW SIGN OF PULMONARY TUBERCULOSIS.

SIR,—As Dr. W. J. Hoyten, in the JOURNAL of February 12th, has very kindly drawn attention to the fact that lowering of the external end of the clavicle is described in my book on *Pulmonary Tuberculosis in General Practice*, may I say that I have always regarded this appearance as an ancient and well known sign of somewhat advanced or extensive disease? "Depression both above and below the clavicle is now greatly more marked, and may sometimes be really present to a notable amount, but be masked by twisting of the clavicle downwards and inwards on its long axis." The italics are mine, and the quotation is from page 422 of Walsh's *Practical Treatise on the Diseases of the Lung*, 1871. This sign has also been described by foreign authors, ancient and modern; but in our own country there is sometimes a tendency towards the indiscriminate quotation of foreign and often dubious authorities, especially Tentonic, and against the recognition of native writers, dead or living, even to the extent of depriving them of such crumbs of fame as may fall from a bibliographical reference.

There is, however, another sign of pulmonary tuberculosis which, although as old as the disease, has not been described previously, as far as I recollect, in any textbook, but which I have noted in many cases. The sign is visibility and engorgement of the cephalic vein in the interval between the deltoid and the pectoralis major. In health the vein is not seen in this place, but when the sign is present the vein is visible throughout its course from the radial end of the dorsal venous arch to the point where it pierces the costo coracoid membrane. This sign is pathognomonic of interference with the venous circulation, from obstruction in the pulmonary capillaries, from diminished intrathoracic suction during inspiration, or from back pressure from the heart, together with wasting of the superficial fat and of the muscles. Consequently, although not an early sign of pulmonary tuberculosis, it may occur in moderately advanced disease, and also in other diseases where the above conditions are present.—I am, etc.,

London, S.W., Feb. 12th.

HALLIDAY SUTHERLAND.

MEDICAL TREATMENT OF ADENOIDS.

SIR,—The interesting letter from Dr. B. G. M. Baskett, on the question of the medicinal treatment of adenoid vegetations as opposed to operation (February 5th, p. 213), calls for certain remarks. I have for years made use of iodine in various forms—such as sodium iodide, potassium iodide, syrup. ferri iod., iodipin, iod-albin, iodoglydine, etc.—in the treatment of a certain class of case of "adenoids."

This is the case in which the chief symptoms manifest are an increased tendency to catch "colds," and the persistence afterwards for two or three weeks of a slight mucous discharge from the nose; there is also usually a tendency to mouth breathing. Iodine will in this class of case, if combined with a change of air to the country or seaside and regular breathing exercises, bring about complete relief. It will be seen that such cases are very slight. Any deafness from Eustachian obstruction, any cervical adenitis or severe and persistent sero-purulent nasal discharge, I regard quite apart from any other indications, as definite signs that operative interference is needed.

The majority of hospital patients with adenoids—at any rate in this city of Manchester with its damp and dirty atmosphere—would be in no way improved by iodine in any form, and operation is the only possible measure. It is only in slight cases that the exhibition of iodine is useful, and here only when the patient may also be placed under good hygienic conditions—and such cases ought to be seen from time to time, as the incidence of an infective fever such as measles or scarlet fever, or of that form of infective nasal catarrh or "sore throat" which seems to attack schools, may bring about such an increase in the size of the adenoid vegetations and in the symptoms generally that operation will now be necessary.

In my experience iodine, although definitely useful in cases of "adenoids," has very definite limitations to its curative value.—I am, etc.,

Manchester, Feb. 10th.

LINDLEY SEWELL.

NASOPHARYNGEAL CATARRH AND TUBERCULOSIS.

SIR,—Surgeon Commander Given, in his paper "Deductions from the statistics of pulmonary tuberculosis," published in your last issue, has called attention to an important factor in the causation of pulmonary tuberculosis when he brings into well deserved prominence the frequently preceding catarrh of the nasopharynx.

In dispensary work one finds that out of an average annual number of 1,000 new cases sent for examination, more than 80 per cent. are suffering from nasal obstruction. Even if there are no signs of external catarrh each nostril should be separately examined, and this examination should not be confined to chest cases, for it is seldom that a "hip" or "spine" does not give a history of previous nasopharyngeal infection.—I am, etc.,

Newport (Mon.), Feb. 13th.

J. LEWIS THOMAS.

Obituary.

JAMES CHARLES MCWALTER, M.D., LL.D.,
HIGH SHERIFF OF DUBLIN.

As briefly announced in our last issue, Dr. J. C. McWalter, of Dublin, died suddenly at his residence in North Circular Road in the early morning of February 5th, at the age of 53. On the previous evening he had attended a meeting in Merrion Square which lasted until after 9 o'clock, and when the members dispersed Dr. McWalter's last tramcar had gone. He made a great effort to reach the other side of the city on foot before curfew, and entered his house in a state of exhaustion. The news of his death caused a painful sensation among all classes of citizens in Dublin.

Educated at the Christian Schools and the Catholic University of Dublin, Dr. McWalter qualified with the licence of the Royal College of Surgeons in Ireland and of Apothecaries' Hall, Dublin, in 1897, taking the D.P.H. in 1900. Later in his career he graduated M.A. and M.D. of Trinity College, Dublin, and M.A. of the Royal University of Ireland, and he obtained many other degrees and distinctions in arts and medicine, both at home and abroad. In 1907 he was called to the Irish Bar, and the degree of Doctor of Laws, both of the National University of Ireland and of Ottawa University, was later conferred upon him.

Dr. McWalter took a prominent part in public life. He was a member of the Senate of the National University of Ireland, a member of the Royal Irish Academy, and had been a governor of Apothecaries' Hall. He was an alderman of the Dublin Corporation and he was appointed High Sheriff of Dublin in 1920. In politics he was a Constitutional Nationalist, who did not conceal his dislike of Sinn Féin. During the great war he served with the R.A.M.C. in the Mediterranean area, retiring with the rank of captain. He was the author of several publications, including a history of the Irish Apothecaries' Hall, and he wrote a great many articles and letters, especially on problems of public health.

A regular attendant at the annual meetings of the British Medical Association, he was vice-president of the Section of Pharmacology and Therapeutics at the annual meeting at Aberdeen in 1914; he was vice-president of the Leinster Branch of the Association. Some years ago he married the daughter of Mr. John Crowley of Clontarf, and she has received messages of sympathy from all parts of the city and of Ireland.

Dr. McWalter's interests were as varied as his character was many-sided; he was known in every circle in Dublin, but more especially among the poor of the city, who have lost in him a generous champion and helper. Modest and unassuming, ever moving about, though without fuss or apparent anxiety; gentle and kindly towards patients or callers as towards opponents in controversy, he was for years one of Dublin's outstanding citizens. In politics, as in everything else, he was outspoken and straightforward, and those who differed from him always acknowledged his transparent sincerity. The writer of a character sketch in the *Irish Independent* describes McWalter as belonging to a type that is fast becoming extinct in Ireland—a type prevalent a quarter of a century ago, but rare to-day—original, elusive, many-sided; of sound common sense one moment, annoying the next, amusing now, bitter then; but taking him all round, whether in or out of one of his moods, a sincere and delightful personality. As a controversialist he was better on paper than in debate. National life was barren in his young days, so he turned to words and allowed his passion for them to overmaster him. "He wrote hard and he spoke hard, yet on the day of his death he had not a personal enemy in all Ireland."

Dr. ROBERT HARRIS, of Southport, died on February 5th, aged 73. He was educated at University College, London, and later at Guy's Hospital. He took the diplomas of M.R.C.S. and L.R.C.P.Lond. in 1869, and graduated M.B.Lond. in 1872. After practising for fourteen years in London in partnership with his father, he removed to Southport, where he continued to practise his profession until his retirement some thirteen years ago. He took great interest in the work of the British Medical Association, and had served as secretary of the Southport Division, and as a member of the council of the Lancashire

and Cheshire Branch, of which he was appointed president in 1918-19. He was an ex-president of the Southport Medical Society. In recognition of his services to the medical profession the local practitioners in 1914 presented him with a silver salver and Mrs. Harris with a silver teapot. Since his retirement from practice Dr. Harris took great interest in public affairs, was appointed to the Commission of the Peace for the borough in 1917, and was a regular attendant on the bench.

WE regret to announce the death, at the early age of 43, of Dr. THOMAS GEORGE MILES, of Ruardeau, Gloucestershire, which occurred from acute pneumonia on February 4th. Dr. Miles's practice was a large one, covering a wide district in the Forest of Dean, and he was attending patients up to the day before his death. The son of a doctor, Dr. Miles was educated at Guy's Hospital, and was a house-surgeon in Plymouth and in practice in Lancashire before coming to Ruardeau twelve years ago. He was local secretary of the Forest of Dean Division of the British Medical Association, and took a large share in the public work of the district. He was a member of the Gloucestershire County Council and of the County Insurance Committee, a keen sportsman, who was until recently honorary secretary of the local Rugby Football Combination, a prominent Freemason, and a high office-bearer in the Order of Buffaloes, an order in which Dr. Miles took a special interest. The widow, who has received many marks of sympathy, is left with three children.

The Services.

DEATHS IN THE SERVICES.

LIEUT.-COLONEL HENRY PEERS DIMMOCK, Bombay Medical Service (retired), died at Sydenham on January 23rd, aged 64. He was born on January 16th, 1857, the son of the late James Augustus Dimmock, bank agent, Ely, educated at St. George's, and took the diplomas of M.R.C.S. and L.R.C.P.Lond. in 1879; subsequently graduating as M.D.Durh. in 1893. He entered the L.M.S. as surgeon on March 31st, 1880, became Lieut.-Colonel after twenty years' service, in 1900, and retired, with an extra compensation pension on April 15th, 1911. His first seven years' service was in military employ, during which he served with the 2nd Biluch Infantry, on the North-West Frontier of India, in the Mairi expedition of 1880-81. Entering civil employ in September, 1887, after four years in various stations, he was appointed obstetric physician of the Jambhaji Hospital, Bombay, and professor of midwifery in the Grant Medical College, Bombay, in June, 1891; and twelve years later, in November, 1903, he became also principal of that college. He rejoined for service in the recent war from August, 1916, to 1918, and was appointed commanding officer of the Holborn Military Hospital, Mitcham, containing 1,000 beds, for which he was awarded the O.B.E. in June, 1919. His strenuous work during that period put a heavy strain upon his health. When plague broke out in Bombay a quarter of a century ago, he served as a member of the special plague committee in that city from March, 1897, to May, 1898. He was the author of a small work on cerebro-spinal meningitis in Indian gaoles.

Universities and Colleges.

UNIVERSITY OF MANCHESTER.

MR. ARTHUR H. BURGESS, M.B., M.Sc., F.R.C.S., surgeon to the Manchester Royal Infirmary, and lately Lecturer on Practical Surgery in the University, has been appointed Professor of Clinical Surgery.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

AN ordinary Council was held on February 10th, when Sir Anthony Bowlby, President, was in the chair.

Issue of Diplomas.—Diplomas of membership were granted to the candidates found qualified at the recent examinations, whose names were published last week (p. 252) in the report of proceedings of the meeting of the Royal College of Physicians.

Diplomas in Ophthalmic Medicine and Surgery were granted to seven candidates (*BRITISH MEDICAL JOURNAL*, February 5th, p. 214).

Central Midwives Board.—Dr. W. S. A. Griffith was reappointed to represent the College on the above Board for the period of one year from March 31st, 1921.

Election of Four Members of Council.—The President reported that a meeting of the Fellows would be held at the College on Thursday, July 7th, for the election of four Fellows into the Council in the vacancies occasioned by the retirement in rotation of Sir George H. Makins, Mr. J. Ernest Lane, Mr. H. J. Waring, and Mr. F. F. Burghard; that notice of the meeting

would be given to the Fellows by advertisement and by circular on March 11th; that March 21st would be the last day for the nomination of candidates; and that a voting paper would be sent on April 5th to every Fellow of the College whose address is registered at the College.

Medical News.

On Monday next, February 21st, at 5.30 p.m., a meeting will be held at the house of the Royal Society of Medicine, to hear statements as to medical education in China. Sir Donald MacAlister, President of the General Medical Council, will be in the chair, and Mr. Harold Balme, F.R.C.S., Dean of the Faculty of Medicine of the Shantung Christian University, Tientsin, will give an address. The American Ambassador hopes to be present, and the new Chinese Ambassador will be represented by Mr. Gwyang King, First Secretary of the Legation. Among others who hope to be present are the Right Hon. Sir Clifford Allbutt, K.C.B., President of the British Medical Association, Sir Alfred Pearce Gould, Sir Francis Chamberlain, Bt., and Sir John Jordan, formerly British Ambassador in Peking.

THE Council of Lysom College will forthwith award "France" Pension of £30 a year to aged medical men in necessitous circumstances, as well as a St. Anne's Home Scholarship to the orphan daughter of a medical man between the ages of 9 and 12. Full particulars can be obtained from the secretary, Mr. T. Bernard Lamb. An announcement appears in our advertisement pages this week stating that applications for admission of candidates for pen-sionships and foundation scholar-ships at T'p-om College, and for an examination for the admission of boys as Council Exhibitors, who pay 50 guinea- a year for education and board instead of 100 guineas, the usual fee, must be received at the office, 49, Bedford Square, London. W C 1 by the morning of March 2nd.

In view of statements which have appeared in the Press with regard to an influenza epidemic, we are informed by the Ministry of Health that, whereas for the week ending February 7th, 1920, the number of deaths from influenza in ninety six great towns of England and Wales was 93, the number for the corresponding week of the present year—the week ending February 5th, 1921—in the same ninety six towns was only 61. The number of cases in the week ending December 25th in the ninety-six great towns was 81, in the following week it was 89, and in the week ending January 8th it was 101, since then it has declined to the figure above mentioned. There is no sporadic outbreak of influenza at Aldershot.

A COURSE of twelve lecture demonstrations on gonorrhoea will be given by Mr. E. R. T. Clarkson and Mr. Malcolm Simpson (Chief Assistants to the Genito Urinary Department of the hospital) on Tuesdays, Wednesdays, Thursdays, and Fridays, at 4.30 p.m. in the Venereal Out Patient Department of the London Hospital, beginning Tuesday, March 1st. Members of the medical profession are invited to attend.

A MEETING of the medical practitioners in Bradford was held on February 10th to consider the report of the Local Medical Advisory Committee upon the scheme for the administration of St Luke's Hospital, Bradford, as a municipal general hospital. The committee reported that the scheme before it appeared to aim at establishing a municipal hospital of such magnitude that it would lead to the extinction of the existing voluntary institutions, and expressed the view that the present is an inopportune time to launch an elaborate and costly scheme such as the medical officer of health proposes. The committee's detailed report was approved by a large majority.

On the occasion of his retirement from practice in Newton Stewart, Wigton-shire Dr. N. J. McKie, who has been in practice there for over thirty years, was made the recipient of a public testimonial, his wife and family also being included. Dr. McKie was formerly vice chairman of the Border Counties Branch of the British Medical Association, and has been well known as a successful practitioner. He is a prominent Freemason, and on the occasion of his leaving the district the local masonic lodge, "St. Ninian" 493, took the opportunity of presenting him with a valuable past master's jewel.

At a meeting of the Royal Sanitary Institute, on Friday, February 25th, at the College of Technology, Manchester, discussions will take place on "The use of open fires for domestic heating," opened by Dr. Margaret J. Henderson, and on "Air pollution," opened by Professor J. Radcliffe. At 90, Buckingham Palace Road, London.

S.W., on Tuesday, March 8th, at 5 p.m., the Institute will again meet, and discussions on "The sanitary engineering side of town planning" and "Town planning of built on areas" will be opened by Mr. Edward Willis and Mr. George Pepler respectively.

A MEETING of the School Medical Service Group of the Society of Medical Officers of Health will be held this day (Saturday, February 19th), at 11.30 a.m., at 1, Upper Montague Street, Russell Square, London, W.C. Among the subjects for discussion are uniformity of medical inspection cards and schedules, and superannuation and security of tenure. Members of the School Medical Service who are not members of the society will be welcome as visitors. The honorary secretary is Dr. Amily Ashenny, Health Department, West Bromwich.

THE annual meeting of the Mental After Care Association for poor persons convalescent or recovered from institutions for the insane will be held on Wednesday, February 23rd, at 3 p.m., at Bidwell Royal Hospital, New Bridge Street, F.C. The chair will be taken by Sir Charles Wakefield, President of Bidwell and Bethlem Royal Hospitals, and the speakers will be the Bishop of Barking, Sir William Byrne (Chairman of the Board of Control), the Hon. John Mansfield (Lord Chancellor's Visitor in Lunacy), and Dr. Nathan Raw, M.P.

The annual congress of the Ophthalmological Society of the United Kingdom will be held on May 5th, 6th, and 7th, at the Royal Society of Medicine, 1, Wimpole Street, W.1. The President, Mr. J. Herbert Fisher, will give his opening address on Thursday, May 5th, at 10 a.m.

Mr. GREGORY JEFFERSON and Dr. A. H. HOLMES have been appointed lecturers on clinical anatomy at Manchester University, the former to deal with the surgical and the latter with the medical aspects of the subject.

SIR NAPIER BURNETT, K.B.E., M.D., has been appointed chief executive officer of the Joint Council of the British Red Cross and the Order of St. John.

At the sitting of Lord Cave's Committee of Inquiry into Hospital Finance, held on February 9th, evidence was given by Mr. Gilbert G. Panter (Secretary) on behalf of the Committee of Management of the Great Northern Hospital.

DR. GUSTAVE MONOD, M.R.C.P., of Vichy, will demonstrate on Wednesday next, February 23rd, at 5 p.m. at the Royal Society of Medicine a series of films in which the rate is retarded in the manner found useful for the study of movement, including the walk of men suffering from various forms of war injuries and the wearers of artificial limbs. The films Dr. Monod will show will include one on the cardio pulmonary circulation obtained in Professor Carnot's laboratory, another giving an analysis of golf shots made at the Institut Mancey, Paris, and a third exhibiting various athletic movements. Dr. Monod brings with him a message from the Association pour le Développement des Relations Médicales of the Paris Faculté de Médecine. The hope is that a definite entente may be established between the French and British professions through the association in Paris and the Fellowship of Medicine in London.

THE London County Council retains the services of three medical men for the purpose of medical examinations in connection with claims arising from tramway accidents. Each is paid a retaining fee of £42 a year, 10s. 6d. for each examination within the county, £2 2s. for each attendance at court to give evidence, and a special fee, based upon distance and time, for examinations outside the county. The time having come for a revision of the arrangement, these medical men asked that the increase of 50 per cent in the retaining fee granted three years ago should be applied to the other fees, in view of the increased cost of postage, telephone, travelling, etc. The Council on February 1st decided not to alter the retaining fee nor the fee of £2 2s. a day for attendance in county courts, but to increase by 50 per cent. the fee of 10s. 6d. for each examination and the fee of £2 2s. a day for attendance in the High Court.

THE Great Northern Central Hospital has graded its accommodation into three sections, comprising 140 beds, in the general wards, 62 beds in the contributory wards, and 18 beds in the private wards. In the general wards, necessitous cases are admitted free, but patients who can afford to do so give from 1s. to 20s., according to circumstances. The contributory wards are intended for those unable to meet the full expenses of medical service and nursing at home, and they give, while in the hospital, from £1 1s. to £4 4s., according to their means, as assessed by the committee. The treatment of patients in the general and contributory wards is undertaken gratuitously.

by the honorary medical staff. The private wards, which have just been inaugurated, are intended for the benefit of patients whose means do not allow of the payment of the usual medical and surgical fees, but who are willing to contribute towards the cost of medical services and maintenance while in hospital. The payments range from 4½ to 6 guineas per week, with a fee for medical service of £1 1s. per visit—maximum fee for medical service, £3 3s. per week. In the event of an operation a charge of £5 5s. will be payable, which will cover the reduced fees of the surgeon and the anaesthetist, and the charge for the use of the theatre. By arrangement with a member of the honorary medical staff and the patient concerned, private practitioners may attend the hospital to share in the treatment. The patient in this case pays the local medical practitioner's fee. In assessing the amount payable by patients the committee will arrange for a rebate of 50 per cent. off the medical fees where the income is the minimum for the private wards, or exceed the minimum up to £100.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are sent to the BRITISH MEDICAL JOURNAL alone and not to the Editor.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitology*, Westrand, London.
2. FINANCIAL MANAGER (Advertisements, etc.), *Adon*; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisecra*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the Association is 16, South Circular Road, Dublin; telephone, 101, Rutland Square.
- Associate, Edinburgh; telephone, 4361, Central.

QUERIES AND ANSWERS.

INCOME TAX.

"G. D. M." bought his practice in March, 1919. He asks whether he can be assessed for 1919-20 on the average of his own earnings as a surgeon lieutenant in the navy over the three previous years.

* * No; the legal basis of assessment is the average profits of the purchased practice over those three years, subject to the proviso that "G. D. M." can apply to be assessed on the earnings of the year 1919-20 if the profits have fallen short from some specific cause since or by reason of his succession to the practice.

"J. L. D." bought a car for professional use in 1914 for £250, and sold it for £200 on joining the army; he has since claimed to deduct £350 cost of renewal, as he has paid £550 for a car no better than the one purchased in 1914 for £250. The Income Tax Commissioners refuse to allow the £350 without giving any reason.

* * Our correspondent's claim appears to be in accord with the principle and specific examples expounded by Mr. Hopkins, an official witness, before the Royal Commission on Income Tax. We advise "J. L. D." to point this out to the local inspector of taxes, and to ask for reconsideration of the question. The appeal lies to the local or special Commissioners of Taxes, provided that the assessment was objected to within twenty-one days of the receipt of the notice of assessment.

"MEDICAL INSPECTOR" inquires as to the expenses deductible from the Schedule E assessment on his stipend.

* * Expenses incurred wholly, exclusively, and necessarily in the performance of the duties of the office can be deducted provided that they are not of a capital nature. It is impossible to give a categorical reply without knowledge as to the precise conditions of the appointment and the degree of

assistance, if any, given by the authority—for example, the provision or otherwise of a medical reference library. *Prima facie*, the expenses mentioned are allowable to the extent to which they are actually laid out in the year in the maintenance, but not the original provision or improvement, of our correspondent's essential equipment.

"INQUIRER" purchased a practice for a certain sum, which he is paying off in annual instalments. He asks whether he can deduct the payments from his practice receipts for income tax purposes.

* * No; the payments are none the less of a capital nature because they are being spread over a more or less lengthy period instead of being made in a single sum.

LETTERS, NOTES, ETC.

THE writer of the obituary notice of the late Dr. F. H. Dayus, printed in the JOURNAL of February 12th, stated that Dr. Dayus "shared with Dr. Dain, of Birmingham, the distinction of being one of the two medical chairmen of Insurance Committees." We now learn that Dr. R. Harding and Dr. E. J. Maclean have long been chairmen of the Radnorshire and the Cardiff Committees respectively; and there may be other medical chairmen of Insurance Committees.

"INCITAMIN."

In our issue of January 29th (p. 179) we replied at some length to an inquiry regarding incitamin, an organic preparation devised by Professor Fischer of Copenhagen for the treatment of wounds and ulcers. The latest contribution to the spirited discussion of this topic in our Danish contemporary *Ugeskrift* is a letter from Dr. E. Himmelstrup in the number for January 20th. He points out that Professor Fischer's paper on this subject suggested an uninterrupted series of successes; at any rate no mention was made of failures. Yet the one case Dr. Himmelstrup has been able to investigate was an utter failure as far as treatment with incitamin was concerned. The patient had suffered for several months from severe and extensive x-ray ulceration. Neither the pain nor the ulceration was affected by the prolonged use of incitamin.

SUPERNUMERARY NIPPLES.

DR. EDMUND CAUTLEY (London, W.) writes: In reply to Dr. Skerrett's inquiry in last week's JOURNAL, polythelia (supernumerary nipples) is not uncommon, and is often associated with polymastia, which is said by Iwai to be present in 5.1 per cent. of Japanese women and in 1.6 per cent. of the men. It is less common in this country. During pregnancy such nipples may become more prominent and more readily erectile. If mammary tissue is also present, pricking and other sensations are felt, as in the normal breast, and turgescence occurs. Occasionally polymastia is the result of a dichotomy of a single gland, or is a spontaneous variation. The peculiarity runs in families and is usually transmitted by females. In Dr. Skerrett's patient transmission was paternal.

DR. D. H. VICKERY (Ministry of Pensions Hospitals, Neath Glam.) writes with reference to Dr. Skerrett's note of supernumerary nipples (February 12th, p. 254): The rarity consists more in finding them well developed. Recently an operation this condition was noticed in a man, and the development was so advanced I had a sketch made. The areolae were exceptionally developed and were studded with hairs. Anyone interested in the matter can gladly have this life-like sketch for inspection.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 38, 39, and 40 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 41 and 37.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not safeguarded.

Advertisements should be delivered, addressed to the Manager, not later than the first post on Tuesday morning, and, if not paid for at the time, should be accompanied by a cheque or cash.

NOTE.—It is the rule of the Post Office to receive no letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

228. X-ray Examination of the Chest in Acute Respiratory Affections in Children.

RUSCA (*La Pediatria*, January 1st, 1921), as the result of his researches, came to the following conclusions: (1) X-ray examination in the child is of considerable diagnostic value in the not infrequent cases in which pneumonia is suspected, although the physical signs do not justify the diagnosis. (2) Lobar pneumonia in infancy is shown by x-ray examination to be more frequent than the ordinary physical signs suggest, while, on the other hand, central pneumonia is quite exceptional. (3) Fully developed lobar pneumonia has a definite radiological picture corresponding to the ordinary physical signs. Both at the beginning and end of the morbid process a shadow can be found on x-ray examination when the clinical signs are still absent, or when they have disappeared entirely. (4) X-rays show the exact situation of hepatization, which is often not found by ordinary physical examination. (5) X-rays may be of some assistance in distinguishing between lobar pneumonia and caseous bronchopneumonia in small children. (6) Bronchopneumonia never shows a triangular area on the screen; the radiological pictures are inconsistent, not always corresponding to the clinical findings, and radiological differentiation of the various forms of bronchopneumonia is impossible. (7) Pleurisy with effusion and empyema show the same radiological picture in children as in the adult. (8) X-ray examination in acute respiratory affections in children, though in some cases it may be of great value, especially in establishing the exact extent of the inflammatory focus, cannot, and ought not to, take the place of the ordinary methods of physical examination, but should be used in conjunction with them in establishing the exact diagnosis.

229. Recklinghausen's Disease.

CASTRONOVO (*Rif. Med.*, September 4th, 1920), in a review of this disease, says that the three cardinal symptoms are cutaneous fibromata, fibroma of the nerves, and pigmentation of the skin. As in other diseases, there may be mixed forms and abortive types. The nerve fibromata may affect any nerve, but most commonly are found in the peripheral nerves and their roots, the cauda equina, and the cerebellum. Secondary lesions in the cerebro-spinal axis are not common, but when present take the form of sclerosis of the cord. The nerve fibromata are seldom single; they appear as easily enucleable tumours in the centre of the nerve trunks, or as voluminous tumours attached to the small nerves. Occasionally the tumours develop in mucous membrane or in internal organs. The skin tumours may reach very large numbers (for example, 7,000 in Profeta's case), and are of all sizes and weight. The genital organs, the soles of the feet, and the palms of the hands are usually exempt. The tumours arise from connective tissue, and consist of fusiform cells with an oval nucleus; they have little tendency to contraction or sclerosis. In the nerves they may start from the endoneurium, the sheath of Schwann, or from the blood vessels and lymphatics of the connective tissue of the perineurium. The pigmentation may be punctiform, macular, or a diffuse greyish-yellow mask-like appearance (*facies fannica*). The disease is frequently associated with congenital lipomata, plexiform neuromata, syringomyelia, and certain other dystrophies—for example, bony malformations. Malignant transformation occurs in 12 per cent. of the cases, according to Gairé. A case (with photographs) of the disease is recorded by the author. Recklinghausen's disease is often congenital and hereditary; of the various theories as to its cause the author favours that which associates it with disease of the endocrine system. Arsenic, opotherapy, abrolysin, and surgical treatment have all done good.

230. Dentition and Febrile Processes.

ABELS (*Wien. Klin. Woch.*, October 28th, 1920) states that hitherto two different views have been held as to the so-called diseases of dentition. On the one hand are those who attribute all possible diseases to the process of dentition, while the other party denies that dentition is responsible for any morbid phenomena. Abels now propounds a third view which, in his opinion, gives the best explanation

tion of the question—namely, that there has been a confusion of cause and effect, the fact being that febrile processes are followed by eruption of teeth. He illustrates this by observations made during a recent epidemic of measles.

231. Trauma and Other Non-specific Influences in Paresis.

MICHAEL OSNATO (*Journ. of Nervous and Mental Disease*, August, 1920) considers the bearing of head injury and other influences on the causation of paresis, apart from a syphilitic etiology. He quotes a series of thirteen cases of general paralysis, nine of which had a history of head injury. The date of the injury and its character are described. In all cases a positive Wassermann reaction was obtained in the blood and cerebro-spinal fluid. Colloidal gold reactions were done in four of the cases, and showed the paretic reaction, and the symptoms described point to paresis, except one which was considered a case of cerebro-spinal syphilis, and improved under treatment. In all of the cases the symptoms began immediately after the injury—that is, a few days in most cases, and not more than a few weeks later in any of them. Considerable interest attaches to the remaining four cases. One was that of a physician who had an operation chancre on his finger, and developed tabes sixteen years afterwards. After developing bedsores and cystitis he fell when trying to walk, and broke his right ankle. Typical paretic symptoms developed almost at once. Of the remaining three, one developed paresis after prolonged etherization, one after influenza, and one after a mental breakdown—psychical trauma. The general course of the disease was the usual one, and treatment gave no better results than in cases uncomplicated by trauma. Osnato suggests several conclusions: That trauma in a syphilitic may give the spirochaetes an opportunity for invasion; that the course of the disease may be hastened by the changes secondary to injury; that toxins, as influenza, alcohol, or other, may have an influence similar to trauma in syphilitics and produce paresis; and that any syphilitic suffering from head injury should immediately be given prolonged rest and active intensive antisyphilitic treatment with a view to killing as promptly as possible any spirochaetes which may have gained access to the brain substance. Lastly, one must be prepared for a possible paretic reaction following infections or prolonged etherization in a known syphilitic.

232. Sudden Death in Pertussis.

NASSO (*Pediatria*, June 21st, 1920) reports the case of a child, aged 14 months, who suffered from whooping-cough for about a month. The paroxysms of cough were sometimes replaced by paroxysms of sneezing, and after one such attack the child suddenly expired. At the autopsy slight lymphatism was noted; the upper air passages, trachea, and large bronchi were free. The lungs were anaemic, with small hyperaemic foci at the base, and a nodule of red hepatization at the right apex; the bronchial glands were slightly enlarged. The cause of death was probably spasm of the glottis. Spasms of sneezing alternating with spasms of cough are occasionally met with in pertussis, but are not common.

233. Tabes and General Paralysis Preceded by Chronic Syphilitic Meningitis.

VINCENT (*Paris méd.*, October 2nd, 1920) relates two cases in which a latent chronic syphilitic meningitis was observed a long time before the appearance of any signs of tabes or general paralysis, and states that no examples of the kind have been previously recorded. The first case was that of a man who contracted syphilis in 1901, and was kept under observation from 1907 to 1919. From 1907 to 1912 he presented no symptoms of nervous disease, but as his wife had had a series of miscarriages he submitted to lumbar puncture, which showed a considerable lymphocytosis. During the next five years—that is, from 1907 to 1912, he was energetically treated with calomel, cyanide of mercury intravenously, biniode of mercury, and later salvarsan; but in 1912 symptoms of tabes developed, and in January, 1919, general paralysis supervened, which proved fatal in the following April. The second case was that of a man who had contracted syphilis in 1904, and from 1911 to 1914 showed considerable cerebro-spinal lymphocytosis,

but no other signs of nervous disease. In spite of active treatment from December, 1913, until August, 1914, signs of tubercle developed during the war, though the exact time could not be determined.

234. Decline of Tuberculosis in Denmark.

JENSEN (*Ugeskrift for Læger*, January 6th, 1921) publishes a statistical paper showing the enormous decline of tuberculosis in Danish towns since 1890. In this year there were 32.38 deaths in Copenhagen from all forms of tuberculosis per 1,000 inhabitants; in 1919 this figure was reduced to 13.24. In the provincial towns the mortality from all forms of tuberculosis fell from 28.75 per 1,000 in 1890 to 11.04 in 1919. One curious finding was this: that while in Copenhagen during the latter half of this thirty-year period the decline in the tuberculosis mortality kept pace almost exactly with the decline in the mortality from all causes, in the provincial towns the decline in the tuberculosis mortality was considerably more rapid than the general decline. The author offers no explanation for this apparently anomalous finding. In 1916 and 1917 there was a slight rise of the tuberculosis mortality, with the result that for the five-year period 1915-19 it was slightly greater than for the preceding five-year period; but the decline was resumed in 1918 and again in 1919—a year in which a record low level was achieved.

235. Tritol (Trinitrotoluol) Poisoning.

RUBINO (*Rif. Med.*, December 4th, 1920) gives the result of an examination of about 100 workmen engaged in the manufacture of tritol. In Italy the toxic effects have not been so severe as in England or America (in New York there were 2,507 cases of poisoning, with 53 deaths, and in England, in 1916 alone, 52 deaths); the author attributes the higher mortality in England to the greater prevalence of alcoholism, which predisposes to intoxication from tritol. He attaches great value to the Webster urine test as an early sign. In view of the great infrequency of dermatitis, he thinks intoxication does not proceed by way of the skin but through the digestive tract and by inhalation. Gases may penetrate the skin. The irritating effect of nitrous vapour on the bronchi is well known, and it also affects the blood. Most workers are affected at the beginning, but after a time get acclimatized; in a certain number later poisoning takes place, and this is more likely if they are affected with any digestive disturbance. Wasting is a common symptom. Jaundice was rare amongst the men examined by him; headache, giddiness, and anaemia were observed. Certain prophylactic measures were recommended: (1) Limitation of the hours of work to six or seven hours, with frequent intervals; (2) mechanical means in the operation of nitration; (3) special working clothes, including masks and gloves; (4) no food to be eaten on the premises, and the hands and face to be washed previously; (5) instructions as to the danger of the work.

236. Lethargic Encephalitis in Switzerland.

BAUER and MAYER (*Rev. méd. Suisse rom.*, October, 1920) state that 29 cases of lethargic encephalitis occurred in the canton of Neuchâtel, or its environs, from February to May, 1920, as compared with 3 during the same period in 1919. The writers describe the following types: (1) cortical type with forms of acute delirium, simulating delirium tremens, general paralysis, and other psychoses, and forms of Jacksonian epilepsy and Broca's aphasia; (2) a classical mid-brain type, myoclonic or lethargic in character; (3) a meningeal type, very difficult to distinguish from tuberculous meningitis; (4) forms of unknown localization, simulating hysteria and other neuroses. The mortality among the 29 cases was 5, or 17.2 per cent.

237. Roughness of the Skin in Tuberculous Subjects.

ACCORDING to GARGIULO (*Rif. Med.*, July 24th, 1920), the subjects of tuberculosis, whether pulmonary or abdominal, develop, in 90 per cent. of the cases, a noticeable roughness and harshness of the skin of the forearm. This, he suggests, may possibly be associated with loss of flesh or with the sweating which is common in tuberculous disease.

238. The Use of Sodium Mörhuate in Pulmonary Tuberculosis.

M. BIESENTHAL (*Amer. Rev. of Tuberc.*, December, 1920) tried this preparation on twenty-five patients, to see if he could corroborate Rogers's statement that it "was the best line of treatment for tuberculosis in general." He injected a 3 per cent. solution in water subcutaneously, in doses of 1 mg., increased by $\frac{1}{2}$ mg. in semi-weekly injections until 1 mg. was reached, and then weekly injections. Altogether

430 injections were given. He found no rapid diminution of sputum, no greater average gain in weight than in those not under this special treatment, no reduction of temperature, and very little improvement in the physical signs. No special or serious reactions were noted. He does not, therefore, agree with Rogers's conclusions.

239. The Capillary Pressure.

KYLIN (*Zentralbl. f. inn. Med.*, July 17th, 1920) measured the capillary pressure with a specially constructed apparatus in 100 healthy men, and found that the readings ranged from 110 to 190 mm. H₂O. He considers it possible, however, that the usual range may be between 100 and 200 mm. H₂O. He also examined the capillary pressure in twenty cases of mild renal sclerosis, in all of which it was normal, and never exceeded 190 mm. H₂O. On the other hand, examination of the capillary pressure in 100 cases of acute glomerular nephritis showed that it was constantly raised in that condition, and to a considerable height, readings of over 500 mm. H₂O being frequent. The highest reading was 750 mm. H₂O, which is equivalent to 55 mm. Hg. On recovery the capillary pressure sank like the arterial blood pressure. It is not unusual for acute glomerular nephritis not to show a rise of arterial pressure. In ten cases of acute glomerular nephritis observed by Kylin in which there was no rise of arterial pressure all showed a distinct rise of capillary pressure. The capillary pressure is, therefore, a valuable means of distinguishing true from apparent focal nephritis.

SURGERY.

240. Etiology and Prophylaxis of Post-operative Jejunal Ulcer.

DENK (*Wien. klin. Woch.*, January 6th, 1921) states that the increase in the number of operations on the stomach and duodenum has been accompanied by an increase in the number of jejunal ulcers observed. This complication is most frequent after gastro-enterostomy for duodenal ulcer and very rare after gastro-enterostomy for an ulcer some distance from the pylorus. Denk considers that gastro-jejunal ulceration at the anastomosis is probably due to disturbances in the healing process of the suture of the mucous membrane due to persistence of silk ligatures and to early administration of solid food. Ulcers situated exclusively in the jejunum have been variously attributed to mechanical, chemical, circulatory, and nervous factors. The best method of prophylaxis, according to Denk, is Billroth's operation or extensive gastric resection, as recommended by Schnitzler, Schur, Plaschkes, and Finsterer. In gastro-enterostomy care should be taken to avoid injuring the mucous membrane, and the same diet should be given for several weeks. When a neurotic element is present, atropine, papaverin, or belladonna is indicated.

241. Rectal Anaesthesia.

BALSAMO (*Rif. Med.*, September 11th, 1920), after a reference to the history of rectal anaesthesia with ether, mentions some of the drawbacks of the method. (1) Deaths have been reported in 8 cases out of 2,500. (2) Distension of the bowel may interfere with operative procedures. There may be: (3) intestinal haemorrhage; (4) incomplete narcosis; (5) collapse and respiratory disturbance; (6) subsequent vomiting and abdominal pain. (7) The procedure is contraindicated in diarrhoea and intestinal disease, especially tuberculous disease. (8) Long preparation of the patient is required, and anaesthesia after the operation is unnecessarily prolonged. The author has given ether per rectum two hundred times, after the method recommended by Gwathmey. Details of the various kinds of operation are given; some were urgency operations—for example, strangulated umbilical hernia, ruptured ectopic pregnancy, Caesarean section, etc. The results were very satisfactory; children seldom retained the injection long, but usually long enough to induce anaesthesia. Insufficient narcosis was observed in about 20 per cent. of the cases. The average amount of ether mixture given was 3 grams of ether for every kilogram of body weight. Vomiting during the operation was never seen; respiratory difficulty very seldom. The only case that gave any trouble was one of severe double compound fracture of the legs where tourniquets had been applied to the thighs; when the tourniquet was released and a wider distribution of the ether in the circulation allowed, the respiratory trouble quickly disappeared. Post-operative haemorrhage which might be attributed to the ether occurred in 3 cases but was only slight. In

one of these cases—a case of plastic surgery of the face—the patient had previously been given five rectal injections of ether at intervals of about a month. Slight diarrhoea was noted in 18 cases.

242 Indications for Operation in Cholelithiasis

HEMENHAIN (*Zentralbl. f. Chir.*, January 8th, 1921) furnishes statistics of 570 operations for gall stone disease. His figures, like those of other observers, show that a large proportion of the patients—in Worms nearly 53 per cent.—come for operation much too late. His first group of cases was composed of 269 relatively simple cases, such as stone in the gall bladder, with a mortality of 1.5 per cent. The second group consisted of 106 cases of cholelithiasis with well marked septicaemia or peritonitis, with a mortality of 14.1 per cent. The third group consisted of 158 cases of stone in the common bile duct, with a mortality of 4.8 per cent., and the fourth group of 37 cases of cancer, with an immediate mortality of 30 per cent. and no ultimate recovery. The second and third groups thus comprised 264 cases with 38 deaths, of which 29, or 76.5 per cent., were due to chronic myocarditis, septicaemia, cholaemia, cholecystitis, and inanition. Operation is invariably indicated in acute cholecystitis with fever and a palpable gall bladder, because, as in appendicitis, one can never tell how the process will terminate. Very good results are to be obtained from operation during an attack of gall stone colic. Operation is also indicated in chronic relapsing gall stone disease as soon as the general condition begins to be affected.

243 Vaccine Treatment in Oto-Rhino-Laryngology

ERATH (*Rev. de lar., d'otol., et de rhinol.*, November 15th, 1920) regards vaccine treatment as an extremely valuable method in the treatment of chronic suppurative affections of the ear, nose, and accessory sinuses when the disease is confined to the mucous membrane. Vaccine treatment naturally does not exclude surgical measures in cases of definite bone lesions such as sequestra, or of cholesteatoma, polyp, and malformations, but it very often renders unnecessary an operation which might be required for suppuration only, as in sinusitis.

244. Pharyngeal Suppuration Secondary to Mastoid Abscess

ACCORDING TO MOREAUX (*Rev. de lar., d'otol., et de rhinol.*, December 31st, 1920), who reports two examples, pharyngeal suppuration secondary to a mastoid abscess may develop acutely with all the symptoms of a peritonsillar abscess, or be discovered only by accident owing to a special examination being made, or owing to some accessory symptom such as chronic purulent expectoration or oral fetor. The diagnosis of pharyngeal suppuration of otitic origin may be difficult, and is established by the history, it being borne in mind that a mastoid abscess may be present after an acute or chronic otitis has cicatrized. In cases of pharyngeal suppuration coexisting with suppurative otitis media, symptoms of pain in the neck, tenderness along the large vessels, and torticollis, are a guide. Bacteriological examination should always be made of the pus from the ear and from the pharynx, and will reveal the identity of the causal micro organisms. The differential diagnosis must be made from peritonsillar abscess, subaponeurotic abscess, and retropharyngeal abscess secondary to disease of the vertebrae.

245 Influence of Age upon Astigmatism

A. W. STIRLING (*Archives of Ophthalmology*, January, 1921) says that the commonly accepted dictum is that a convex cylinder "with the rule" tends to be vertical, and a concave lens horizontal, the reverse in either case being spoken of as "against the rule." His figures go to show that the "rule" that the axis in hypermetropic astigmatism tends to be vertical, while correct for the young, is incorrect in the elderly; they indicate that there is quite commonly a rotatory movement of the axis, proceeding slowly with the passage of time, they further show that in hypermetropic and in myopic eyes there is a definitely greater tendency for the meridian of greater corneal convexity to wheel towards the nose than away from it—that is, of course, if the astigmatism is corneal in origin and not lenticular, a fact which can be settled by using the ophthalmometer. In the later decades of life a large proportion of lenses show peripheral striae, and it may be that these changes may have some thing to do with changing the axis of the cylinder, but, apart from this fact, Stirling's figures go to prove the truth of his assertion. The whole question of the change of the axis in astigmatism is one requiring research by one of the older ophthalmic surgeons now in practice, for

it is only by examining a large series of records of cases extending over many years that positive evidence can be obtained. Stirling's paper does not go into any of the effects of astigmatism, but it is a valuable attempt to throw light on a part of the subject which up till now has been largely or altogether neglected.

OBSTETRICS AND GYNAECOLOGY.

246 Prognostic Significance of the Escape of Meconium.

GEJROT (*Hygienica*, December 16th, 1920) has investigated the relation of the *intra partum* escape of meconium to the incidence of asphyxia and stillbirth in a series of 6,437 births (all head presentations) recorded at a maternity hospital between January 1st, 1917, and September 30th, 1919. In 369, or 5.72 per cent., meconium escaped *intra partum*. Of these 369 infants, 308 were alive and well at birth, 37 were slightly and 11 were severely asphyxiated (only 5 of the latter class were resuscitated), and 13 were stillborn. When the cases were classified according as the meconium escaped before or after the rupture of the membranes, it was found that the prognosis for the infant was determined much more by the length of the interval between rupture of the membranes and completion of labour than by the escape or retention of meconium. The author concludes that slight asphyxia *intra partum* does not provoke the escape of meconium, whereas severe asphyxia usually does so. After the escape of the liquor amnii, he holds that the pressure of the maternal parts may alone be sufficient to force meconium out of the infant's gut. In most cases, however, he regards the escape of meconium *intra partum* as a juxtaphysiological act dependent on a certain liveliness of peristalsis. In this connexion he refers to the classical experiments of Porak and Runge, who found that large doses of quinine sulphate, given to the mother, caused the escape of meconium *intra partum* in about 50 per cent. of the infants, and this effect was traced to the peristaltic action of the drug on the infant's gut.

247. Treatment of Hyperemesis Gravidarum.

PERX (*Gaz. hebdomadaire des Sciences Méd. de Bordeaux*, December 12th, 1920) records two cases of intractable vomiting of pregnancy. In the first the ordinary therapeutic measures and an injection of hot serum were attended by failure, but a cure was at once established by injection of several cubic centimetres of the serum of a pregnant woman. In the second case such an injection failed, as also the more usual treatments, a slow improvement took place after a dilatable bag had been placed in the vagina to correct a somewhat exaggerated uterine anteversion.

248. Delivery through a Cervical Laceration

V. HEISS (*Zentralbl. f. Gynäk.*, November 27th, 1920) records two cases presenting features of forensic interest. In the first, inevitable abortion in a primipara, aged 32, was treated by cervical dilatation (Hegar's sound, to number 7) and introduction of a bougie, subsequently further dilatation (to number 12) was performed, and a Braun's bag introduced into the uterus. Six hours later the five months foetus and placenta were found to have been expelled through a transverse tear situated in the posterior cervical wall 3 cm above the external os. The second patient, aged 24, was nulliparous, a five months pregnancy was interrupted on account of preperal insanity. The tear was similarly situated to that of the first case. The operative treatment in each case was performed deliberately and carefully, so that gross injury to the cervical wall could be excluded as a cause of the tears, which the author attributes to rigidity of the cervix.

249. A Physical Sign of Ovarian Cyst

DANIEL (*Gynec. et Obstet.*, 1920, 1, 6) gives an account of the sign which he described to the Urological Society of Bucharest in December, 1919, it may be of value, he thinks, in the diagnosis of ovarian cysts. Standing at the patient's right, with his face directed towards the patient's pubis, the examiner, with his left hand, pushes the swelling to the right side of the abdomen, at the same time lifting it in an external direction, the right hand, through the thickness of the abdominal wall, seizes the wall of the tumour between the thumb and two fingers. The result of this "pinching" is that the portion of the cyst wall which has been taken up glides suddenly away from the fingers. This test is applicable especially to flaccid, unilocular, thin walled cysts of moderate size.

PATHOLOGY.

250.

Gummata of the Lung.

ELIZABETH (C.R. Soc. Biologie, November 27th, 1920), who has studied several cases of pulmonary gummata, says they may be observed at any age and may accompany other syphilitic lesions of the lung. They have no typical localization, being vascular in origin, but, as the vessels accompany the bronchi, gummata are always related thereto. Their number is limited: they may exist in one or both lungs. Their size is proportional to the importance of the vessel primarily affected; in general they vary in size from that of a pea to that of a turkey's egg. Their origin explains how central gummata of moderate size are spherical, whilst peripheral gummata are cuneiform. They are white in colour, yellow when necrosis takes place, and reddish if there is congestion. Sometimes they are marbled by anthracosis. The initial vascular lesion is almost always an acute endarteritis. Soon after its formation the gumma is crowded with spirochaetes, but as necrosis and cellular disintegration advance they can no longer be found. Around the gumma there is a zone of congestion and a reaction on the part of the pulmonary tissues. In the alveoli may be found an albuminous exudate, with epithelial cell desquamation and immigration of leucocytes. Then there appear the fibroblasts, lymphocytes, plasma cells, giant cells, and the other cells which go to form granulation tissue. The pulmonary tissue, even when richly infiltrated with spirochaetes, does not show gummata but merely pneumonic lesions, unless there has been obliteration of the vessels. The inflammatory zone on the periphery may become fibrous (fibrous gumma), and this tissue, becoming hyaline, may allow of infiltration by calcium salts (the calcified gumma). The gummatus necrosis affects a variable number of bronchi, which may ulcerate, and a cavity may thus be left which becomes infected secondarily, giving rise to the suppurating gumma. This may or may not be evacuated by the bronchi. If an infection supervenes gangrenous complications may ensue.

251. The Different Types of Pneumococcus.

THOMSEN and CHRISTENSEN (Hospitallstidende, November 24th, 1920) have carried out investigations at the Serum Institute in Copenhagen which indicate that the differences between the various types of pneumococcus are practically as great as between pneumococci and other micro-organisms found in the sputum. Just as pneumococci can be obtained in pure culture by injecting a mixture of micro-organisms into the peritoneal cavity or subcutaneous tissues of a mouse and cultivating the pneumococci found in its blood or spleen, so the various types of pneumococcus may be separated by the following procedure: A pure culture of Type I being required, a mixture of Types I and II are injected together with the specific serum corresponding to Type II. Type II being thus made innocuous, culture of the mouse's blood yields only colonies belonging to Type I. The authors record several experiments, one more or less accidental, illustrating the distinctness of the different types. Working with what they thought was a pure culture of Type I, they anticipated that 0.1 to 0.2 c.cm. of the homologous serum would protect the mouse from an injection of 0.05 to 0.1 c.cm. of the bouillon culture. But the mice invariably died, and all the pneumococci cultivated from the blood, spleen, and peritoneal cavity were found to belong to Type III. Thus, the presumption that the original culture contained only Type I proved to be erroneous, and when at last an absolutely pure culture was obtained, 0.2 c.cm. of the homologous serum gave immunity to an injection of 0.05 to 0.1 c.cm. of bouillon culture. The authors conclude that these and similar experiments plainly indicate the necessity for using a type-specific serum in the treatment of pneumococcal infections.

252. Indol in Cerebro-spinal Fluid in Influenzal Meningitis.

ACCORDING to RIVERS (Journ. Amer. Med. Assoc., November 27th, 1920), eleven out of twelve strains of *B. influenzae* found in cases of influenzal meningitis were indol formers. With the exception of *B. coli*—an exceedingly rare cause of meningitis—none of the other organisms usually causing meningitis (meningococci, pneumococci, streptococci, or staphylococci) forms indol. To an ether extraction of the cerebro-spinal fluid is added Ehrlich's reagent (para-dimethylamidobenzaldehyde, 4 parts; absolute alcohol, 380 parts; concentrated hydrochloric acid, 80 parts): the presence of indol is signified by an old-rose coloured ring at the plane of contact. The test is negative in the fresh

fluid, but faintly positive after a few hours' incubation. If the growth of the bacilli is aided by the addition of one drop of sterile blood to 10 c.cm. of the spinal fluid before incubation the reaction is accelerated and intensified, becoming in some instances strongly positive in three hours.

253. Complement Fixation Tests in the Hosts of *Bothrioccephalus*.

BECKER (Finska Läkarsällskapets Handlingar, November-December, 1920) has carried one step further the investigations of Tallqvist and others into the serological problems associated with the *Bothrioccephalus latus*. Applying the complement fixation test to 58 persons whose faeces contained the eggs of *Bothrioccephalus latus*, he obtained haemolysis with a *Bothrioccephalus latus* antigen in 50 per cent. of all his cases, whereas the reaction was positive only in one-ninth of the 92 "controls." The author is very doubtful as to the reaction being strictly specific, for he obtained positive reactions in cases of *Bothrioccephalus latus* tested with an antigen obtained from an extract of taenia, as well as with the hosts of taenia whose serums were tested with a *Bothrioccephalus latus* extract. The author notes that Jerlow's investigations point in the same direction as his own.

254. Blood Ferments in Pregnancy, Carcinoma, and Pulmonary Tuberculosis.

GRÖNBERG (Finska Läkarsällskapets Handlingar, November-December, 1920) has applied Abderhalden's test to the diagnosis of pregnancy, carcinoma, and pulmonary tuberculosis, taking the precaution to eliminate bias by testing the serums without knowing which belonged to "controls." He obtained a positive reaction to placental tissue from the serums of every one of the 28 cases of pregnancy in the first to the ninth month; none of the 19 "control" serums from non-pregnant persons gave a positive reaction. He also tested the serums of 23 patients suffering from carcinoma in various stages, and all gave a positive reaction to an extract of carcinomatous liver. The results were equally distinctive in the case of pulmonary tuberculosis, all the 34 cases of this disease giving a positive reaction to an extract prepared from tuberculous lungs. In none of the "controls" was a positive reaction obtained. In spite of these good results the author insists that Abderhalden's test will have to be much simplified before it can be of any value in hospital practice, and he finds that the omission of only one of the many details of the technique is sufficient to render the test valueless. To begin with, the investigator must make sure that his dialyzer is in perfect working order, and during 1918 and 1919 the author had to reject as many as 70 per cent. of the dialyzers tested.

255. Neutrophile Leucocytes in Pulmonary Tuberculosis.

ACCORDING to ARLOING (Journ. de Med. de Lyon, December 5th, 1920), investigation of the neutrophile leucocyte blood count according to Arneeth's formula has diagnostic and prognostic value in cases of pulmonary tuberculosis. The changes in the Arneeth figure are determined by the gravity of the infection and by the patient's power of resistance, rather than by the degree of advancement existing at the particular moment in the course of the infection.

256. A Spirochaete Associated with Psoriasis.

RASCK of Christiania reports the discovery, both in the skin and in the circulating blood of persons suffering from psoriasis, of a spirochaete which multiplies by sporulation, and is called by him *Spirochaeta sporegonum psoriasis*. In sections of the skin the parasite has a thickness of 0.25 to 0.5 μ and a length varying between 5 and 50 μ . In the blood detection of the spirochaete is difficult; it is most frequently found in rings or small spiral forms, some of which lie within the erythrocytes. Macrogametes and microgametes are also described and illustrations are given of these and the other parasitic forms.

257. An Unusual Case of Sarcoma

KUMEN (Wien. Klin. Woch., December 9th, 1920, records the case of a woman, aged 22, who from the age of 9 had had a nodule in the left frontal region which soon began to ulcerate. The condition was regarded as a gumma due to inherited syphilis, and for ten years anti-syphilitic treatment was employed without success. When the patient was seen by Kumén the Wassermann reaction was negative, and histological examination showed that the growth was a mixed-celled sarcoma. Kumén regarded it as a primary sarcoma originating in the bone and periosteum.

In Winter

'BYNOL'

For those who feel the cold.
A most palatable form in
which to take a daily ration
of active metabolised fat.

"Bynol" is a combination of Cod-Liver Oil and Malt Extract, having exceptional nutritive power. The Oil used in its manufacture is a pure product, in the preparation of which Messrs. Allen & Hanburys have been directly engaged for over half a century at Lofoten and Söndmör, Norway. Medical reports show that it is one of the best agents for arresting loss of weight and increasing capacity for assimilation.

CONTAINS 30% PURE COD-LIVER OIL
YET TASTES LIKE A SWEETMEAT.

Allen & Hanburys Limited,
37, LOMBARD STREET, E.C. 3.

Glaxo Factory at Mata-Mata, New Zealand.

Glaxo Factories in New Zealand

OUR four factories in New Zealand are the largest in the world devoted entirely to the production of dried milk. Each factory is the centre of a dairying district, for the milk must be delivered within two hours of milking time. From the milking of the cows by machinery to the final packing of the powder, every scientific method available is utilised to ensure a powder of high bacterial purity. From first to last, neither the milk nor the powder is touched by hand.

*The bacterial count of reconstituted
Glaxo averages less than 500 per c.c.*

Glaxo

STANDARDISED DRIED MILK
FULL-CREAM, HALF-CREAM, THREE-QUARTER-CREAM

**for Infants, Invalids, the Aged
and General Household Use**

GLAXO (Medical Dept.), 155, GREAT PORTLAND ST., LONDON, W.1

Proprietors: Joseph Nathan & Co. Ltd., London and New Zealand.

The appearance was not atrophic; she had grown to some extent, but the condition of the tissues showed that development had been abnormal. The dystrophic and atrophic forms are identical in their origin, both being due to a diet consisting chiefly of carbohydrates, particularly starch, over a long period. I therefore prefer to call these complaints "dystrophia amylogenetica," in order to distinguish them from other forms.

From my rather large and gradually accumulated experience of these regrettable diseases, it appears that it is the delicate and newly-born infants that are most susceptible to the atrophic form, and the stronger and somewhat older ones that mostly suffer from dystrophy, particularly if from time to time they have had a little milk, or milky foods, in addition to the carbohydrate diet.

The peculiar rigidity and tone of the muscles often observed show that they have become changed. This was first observed and described by Gregor, and more thoroughly later by Czerny and Keller. The pronounced cases show opisthotonos and an elastic resistance of the muscles. This was present in the first and the last of the above quoted cases. It is comparatively easy to straighten out the contracted muscles, but they relapse at once as soon as released. This hypertonicity is a serious prognostic sign, but it disappears easily and quickly if the patient recovers. As far as I have been able to observe, it is not related to infantile tetany, which it somewhat resembles.

Common to all children fed on a carbohydrate diet is their great susceptibility to all infections. These children nearly always have some infection, most often of the mucous membranes or a simple dermatitis. When serious acute infections set in they will as a rule react with an enormous loss of weight, due to the surplus water in the tissues suddenly being excreted.

The prognosis of these cases is always very serious and distinctly unfavourable when the vital parts are degenerated.

The most important point in the treatment of these children is careful nursing and the use of stimulants. Furthermore, their diet must be altered so that they obtain the substances they have been without for so long—that is, protein and fat. The best way of doing this is to give them a wet-nurse. If one is not available they must be fed on a diet the basis of which is sterile milk, diluted according to age. Care must be taken, however, not to give too large quantities at first. In particular, when giving cow's milk it is necessary to be very careful, as by taking more than can be digested the child might get chronic dyspepsia or genuine atrophy.

It is a mistake also suddenly to stop the supply of carbohydrates, and still worse to put these miserable children on a diet of water or tea, from which I have often seen the most disastrous results. When the milk diet is started the children must be given as much carbohydrate as they can digest at their respective ages. The best course to pursue is, naturally, to employ a wet-nurse at the same time, and in the most serious cases this is the only means of saving the child's life.

In these cases the faeces become not only sour and fermented, but foetid and irritating; the skin of the buttocks gets red if the soiled napkin is left in contact with the child's skin only for a short time. If the irritation is repeated many times, the skin will be affected by weeping intertrigo all over the napkin area. It is, however, not only the skin which shows the effect of the irritation of these evacuations. The mucous membranes of the intestines, particularly the large gut, reacts at first with slimy secretion, later with haemorrhage, and with brisk peristalsis. As a consequence the child is restless owing to attacks of colic and frequent foul-smelling evacuations. Gradually there ensues a typical colitis, which in many cases is very serious. I have termed this disease "colitis amylogenetica" because of its association with carbohydrate, particularly starch. It occurs in a mild form in the younger infants; only the older and stronger children show characteristic "colitis amylogenetica," and my experience indicates that it is more frequent amongst children in the country. The reason why it is so frequent must, I think, be sought in the prolonged and ill-advised use of the so-called constipating diet.* Another cause of its frequency is no doubt to be found in the disinclination of

many doctors to administer milk and milk preparations to children suffering from diarrhoea, though a milk diet is undoubtedly in most cases the best treatment for chronic infantile diarrhoea. Even in the case of infectious toxic cholera infantum a milk and water diet is much to be preferred to barley or oatmeal water.

I have seen quite a number of children wrongly treated by means of a long-continued constipating diet, and many of them have been in a most miserable condition, particularly when they have been simultaneously loaded with bismuth and silver nitrate, combined with enemas of the latter. I have even seen children become scorbutic under this treatment.

The evacuations may remain watery in spite of the milk diet, which contains only trifling quantities of carbohydrates. It may in these cases be necessary to give the intestines a complete rest, by giving the child for one or, at the most, two days, boiled water only, or weak tea, without milk or sugar, but with saccharine if necessary. On the second or third day milk diet may be started (one part of milk and two parts of water); and at the same time may be given increasing quantities of protein milk. It is not easily fermentable, and therefore is most suitable for the treatment of these cases of chronic colitis. It is made as follows:

To one litre of rich milk is added one teaspoonful of Hansen's liquid rennet. The milk is then placed in a water bath at a temperature of 42° C. to 43° C. for half an hour; it is poured through gauze, when the coagulum is collected and the whey drained off. The casein is then pressed through a fine sieve, and this is repeated ten times. The casein is mixed with half a litre of water. After mashing the casein with an equal quantity of water, it is readily stirred through the sieve. The protein milk is now boiled with continuous stirring and the desired quantity of sugar added (usually 30 grams of castor sugar). After the addition of sugar the milk is quickly cooled with continuous stirring, and then once more passed through the sieve. The prepared protein milk must be kept in a cool place.

Apart from the diet, I administer preparations containing tannin, preferably acorn cocoa in milk. If it does not agree I use albumin tannate, which has the advantage over metallic salts of being non-toxic. It can be safely given in doses of a couple of grams a day for a long time, even to quite young children. In some cases bismuth salts will give better results, the best being bismuth subsalicylate. If, however, the motions are not stained black, the drug may be stopped, as it is having no effect. As bismuth is a poison, it should never be administered for a long period, and it ought to be a fixed rule never to give bismuth, or preparations containing tannin, to a child when on a diet of water or tea. These constipating drugs will only give satisfactory results when taken with milk and milky or other foods.

The oatmeal and barley-water diet will generally be sufficient in cases of ordinary acute dyspepsia, particularly in those frequent cases where the diarrhoea is due to overfeeding with milk and milky foods, causing a pronounced protein decomposition in the intestines. Here it is essential that the barley water should be thin and never sweetened with more than 2 per cent. of cane sugar. Such a diet is meant to be a starvation diet, intended to give the intestines a rest. In the case of an ordinary diarrhoea, the bowels will act normally after a few days of such a constipating diet, and the children may then gradually be given their usual food.

By the term "milk," as used above, is understood good fresh milk which has just been brought to the boil. Raw milk might have just the opposite effect, and this is the reason why children suffering from these intestinal complaints should always be given boiled milk.

At the annual meeting of the Society for the Prevention of Hydrophobia, held at the Farmers' Club on February 1st, Major John Penberthy, ex-president of the Royal College of Veterinary Surgeons, was elected chairman of the committee. The annual report stated that experience of the outbreaks of rabies in this country during the past two years had confirmed the society in its policy of advocating universal muzzling of dogs for a limited period. The utility of attempts to stamp out rabies by muzzling dogs in limited areas has again, it is stated, been demonstrated by recent experience. Mr. F. W. Fletcher, F.C.S., Windsmill, Enfield, Middlesex, has been elected honorary secretary in the room of the late Mr. Frank Karslake, one of the founders of the society.

* During this treatment the child is often given only arrowroot and water, or barley water.

SAPRAEMIC GLYCOSURIA.*

BY

CHARLES GASKELL HIGGINSON, M.A.LOND.,
M.D.DURHAM.

A NEW truth needs much tenacity of life, for few men like to be disturbed in the opinions that they have been at the pains to form; and I am now venturing to expound once again a true doctrine which, though it was well established twenty-two years ago, has not yet been properly diffused through the medical profession, but has had a narrow escape from oblivion. An illness of my own is the reason why this exposition falls to my lot.

In July, 1909, when I was working in a Berkshire sanatorium, I was suffering so much from a hard carbuncle, four inches in length by three in breadth, almost mesially situated where the occiput joins the neck, that I determined to consult Mr. X., of Harley Street. While waiting for my cab I tested my urine, so as to save the surgeon some trouble. I found that Fehling's solution precipitated copper, indicating that I had glycosuria; and a brother practitioner, concluding that I had diabetes as the foundation for my carbuncle, made to his friends a confident prognosis of my imminent death. My own view was that, in any case, Mr. X. would operate, and that, even if he did not, no harm would be done by consulting him.

As I had no thirst nor hunger, nor emaciation nor polyuria, I doubted whether I had diabetes, and I let my thoughts stray among the exceptional glycosurias of the textbooks. Still, I went to Harley Street thinking that, on the whole, the balance of probability was in favour of diabetes, that I should not live long, and that perhaps, like my grandfather, I ought to be contented with the fifty-one years of life that were already mine. After a swift examination, Mr. X. said: "Don't be surprised or afraid if you get glycosuria with this great carbuncle; you will probably have it." I replied: "Pray do not trouble to prophesy; I have it already." Then Mr. X. uttered, with the utmost confidence, these unexpected words: "And you will lose it." He told me that a fellow-resident of his at St. Thomas's Hospital, now Sir Cuthbert Wallace, had proved that the glycosuria of carbuncle and gangrene was commonly not the cause of those diseases, but that the sapraemia from the carbuncular or gangrenous focus was the cause of the glycosuria, just as phloridzin or other poisons caused glycosuria; and that Mr. Wallace had even gone one step farther, and had found that, while glycosuria would appear in the normal person after eating half a pound of glucose, yet in a person whose carbuncle was not quite sufficiently poisonous to produce glycosuria unassisted, glycosuria would appear on his eating (according to the degree of poisoning) one, two, four or six ounces of glucose. Thus, he jokingly added, there was no excuse for our failing to understand the boast of men who said that they had cured diabetes by amputating a leg! The patient would have been suffering from sapraemic glycosuria generated by a gangrenous focus on the leg, and amputation would have cured the glycosuria by removing its cause. So I endured the cruciform incision, and in three weeks my enemy had sloughed away, and I was free alike from carbuncle and glycosuria.

Six months afterwards I consulted a distinguished physician and told him the facts. He smiled incredulously and at once asked for a specimen of my urine, and he was amazed at finding no sugar. In order to see how normal I was as regards my saturation point for glucose a year after my illness, I found that four hours after I had eaten half a pound of glucose my urine contained $1\frac{1}{2}$ grains of glucose to the ounce, according to both methods, Roberts's and Pavy's; in six hours I found no glucose. (Some days afterwards I tried to eat a pound of glucose, but vomited after 13 ounces.) So I must be considered normal as regards my saturation point, which, as regards alimentary glycosuria, is registrable at eight ounces of glucose. Never since have I had glycosuria, alimentary or sapraemic, nor tried to get it.

History of the Doctrine.

Thirty years ago it was held that "diabetes offers an almost positive bar to any kind of operation" (Treves's

Operative Surgery, i, p. 18, 1891). The present writer, while a student, frequently saw patients suffering from gangrene left to die unhelped by operation because glucose had been found in their urine, and it was through investigation of cases of gangrene complicated by glycosuria that truer views were first reached.

In the *Medico-Chirurgical Transactions*, vol. 75, 1892, is a paper by Mr. W. G. Spencer on amputation in diabetes mellitus. After recording the cases on which he bases his conclusions, Mr. Spencer says:

"Such stress has been laid upon the danger from inflammatory complications in diabetes mellitus that many writers condemn operative procedure without qualification, or at least omit to state the indications for it. Yet there is enough evidence, I believe, to show that by the timely adoption of major amputations life may be prolonged and the amount of sugar excreted reduced to a minimum (the italics are mine) in cases where the attempt to effect this by medicinal treatment, in the presence of a severe inflammatory lesion, has quite failed."

Here we have the definite statement that glycosuria may be reduced to a minimum by the removal of a septic focus. How very near he came to the complete discovery of the true doctrine! Again he says: "To put the conclusions in another form. Diabetic gangrene should be operated upon by following the rules already established for other forms of gangrene." Here we have a direct contradiction of Sir Frederick Treves's statement of the previous year, that "diabetic gangrene of a limb is scarcely within the scope of surgical measures; an amputation in such a condition is almost invariably fatal." Sir Frederick Treves, in view of the articles of Mr. Spencer and Mr. Rickman Godlee, rewrote in subsequent editions his own views in the light of theirs.

In the next volume of the *Medico-Chirurgical Transactions*, vol. 76, 1893, Mr. Rickman Godlee (now Sir Rickman Godlee) wrote an article entitled "On Amputation for Diabetic Gangrene." He writes to much the same effect as Mr. Spencer, and definitely denies the doctrine of 1891:

"In truth the introduction of the antiseptic principle has rendered operations upon diabetics very much less formidable than they used to be when most of the present textbooks on surgery were written. The weakened tissues may be, and often are, able to withstand the mere mechanical injury of an operation and endure this as well as the irritation. At the same time it must not be forgotten that antiseptics can do away with the danger of coma or heart failure following an operation, though their wise employment may immensely diminish the chance of sloughing of the flaps."

Here Sir Rickman definitely singles out the successful use of antiseptics as the chief cause of the newly discovered comparative safety of operations on so-called diabetics. The next year, in the *St. Thomas's Hospital Reports*, New Series, vol. 22, 1894, there appeared an article by Sir Cuthbert Wallace on "A Case of Gangrene of Foot with Sugar in the Urine successfully treated by Amputation."

"The amount of sugar," he says, "rose for the first three days after operation—560, 1,360 and 1,400 grains being the respective amounts in twenty-four hours. From this time the quantity fell, except for an occasional rise, continuously until the fifteenth day, when the amount was only 190 grains." Then for three days there was only a trace, when, on the nineteenth day the amount rose to 234 grains, to fall next day to 60 grains. On the succeeding day there was a trace, after which the sugar ceased entirely."

Again: "It happens occasionally that after amputation the sugar disappears or is greatly diminished, and this seems to suggest that it is possible that the gangrene may cause the presence of sugar, possibly through the absorption of septic products." (Italics mine.)

We have often noticed the remark of the textbooks and teachers of to-day that "transient glycosuria may be associated with a carbuncle," which shows that we ought now to be ready for the true theory to fit the observed fact. Formerly the glycosuria used to be considered to be the predisposing cause of the gangrene or the carbuncle associated with it. Here, for the first time, we have the suggestion strongly conveyed that, on the contrary, the sapraemic condition may be the cause of the glycosuria.

In the *Lancet* of December 23rd, 1899, Sir Cuthbert Wallace published another paper on "Gangrene Complicated by Glycosuria." Here we find the whole theory of transient glycosuria elaborated, and based on the observation of typically septic cases of gangrene, carcinoma of rectum, ulcer of rectum, erysipelas, lymphangitis, and carbuncle.

* A paper read at the Medical Institute, Birmingham, before the British Medical Association, on December 16th, 1919. Revised, January 18th, 1921.

The Saturation Point.

There is in normal human blood glucose to the amount of about 1 per 1,000. In diabetes the blood may contain from three to six times as much. The portal vein may in normal life contain 4 per 1,000. This glucose, $C_6H_{12}O_6$, on reaching the liver is arrested there, and stored in the form of glycogen, $C_6H_{10}O_5$, till it is served out to the blood again gradually, in another form, for the needs of bodily heat and work, etc. Normally the liver is not surcharged with glycogen, nor the blood with sugar. That is to say, in Sir Cathbert Wallace's language, that the saturation point is normally not reached. But when, either because of the liver's insufficiency as a storehouse of glycogen, or because too much glucose is poured into the blood stream, the blood is surcharged with glucose, the saturation point is said to have been reached and passed. Then the blood excretes its surplus glucose into the urine, and glycosuria occurs.

Now the saturation point is by no means constant, and if for any reason it falls, it may happen that even the normal amount of glucose in the body may, through the refusal of the liver to secrete it as glycogen, accumulate excessively in the blood, and the excess may be excreted by the kidneys in the urine. In other words, there may be hyperglycaemia, and consequent glycosuria, merely because of a temporary failure on the part of the liver to secrete from the blood the due amount of glycogen; the saturation point is lowered for the body and hyperglycaemia necessarily follows.

Now one of the most important causes of the lowering of the saturation point is sapraemic poisoning, and in this fact lies the true explanation of the transient glycosuria that is associated with carbuncle or gangrene. As an instance of this, Sir Cathbert Wallace mentions his Case No. 5:

"A woman, aged 65 years, was admitted into the hospital with a carbuncle of the back of seven weeks' duration. The urine contained 300 grains of sugar in the twenty-four hours. The slough was excised, and the sugar disappeared from the urine in nine days, and was still absent six weeks later." There was no symptom of diabetes in this case except the glycosuria, and the diet was unrestricted.

Again, suppose that the saturation point remains steady. Even so the normal man can pass it if he introduce enough glucose into his blood stream. I myself passed it by eating half a pound of glucose at 6 o'clock one morning.

"It has been shown," says Sir Cathbert Wallace, "that all persons possess a saturation point; that is to say, that sugar will appear in the urine if a certain quantity of carbohydrate is taken at a meal. A healthy man can dispose of 300 grains (say 9½ oz.) of glucose at a meal and yet none will appear in the urine. This is not so with a patient suffering from septic absorption, as in such a case 50 grains (say 1½ oz.) of glucose will often pass into the urine." Of his Case No. 8, a man of 31, admitted on May 29th, 1893, with diffuse cellulitis-cutaneous erysipelas of the arm, Sir Cathbert writes: "The urine was acid, with a specific gravity of 1020, and contained no albumin nor sugar. On the 31st 100 grains (say 3 oz.) of glucose were given, and the urine passed in the next twelve hours was collected and found to have a specific gravity of 1020, and to contain sugar. Fermentation with yeast reduced the specific gravity to 1016 (that is to say, the urine contained four grains of sugar to the ounce). On June 23rd the wounds were healing well, and the temperature was normal. The patient was now 19 oz. of glucose."

In Case No. 10, a man, aged 54 years, was admitted into the hospital for a carbuncle on the neck of the size of a saucer, which he had had for six weeks. Fifty grains (say 1½ oz.) of glucose were given on two successive mornings, and on the second occasion sugar was found in the urine, which on admission had been described as "1016, acid, no albumin, no sugar." Fermentation reduced the specific gravity by four points (that is, the urine contained 4 grains of sugar in 1 oz.). The carbuncle was scraped, and ten days later another 50 grains of glucose were given, and again sugar appeared in the urine. Fifty grains on the two successive days produced no sugar, nor did 75 grains on the next day. A week later the patient was tested up to 150 grains (4½ oz.), but the urine continued normal."

Dr. R. T. Williamson (whose great learning and industry all of us whom he taught at the Manchester Royal Infirmary have reason to remember) quotes Von Noorden as saying that in a healthy person glycosuria will be caused by a single dose taken on an empty stomach of from 180 to 250 grains of glucose (6 to 8 oz.).

Quoting Nannyn, he says that if distinct glycosuria occurs when a man takes 100 grains (3 oz.) of glucose two hours after a standard breakfast of 1 litre of coffee and milk and 80 to 100 grains of bread, then the saturation point is distinctly lowered. Von Noorden found that in four out of fifteen obese persons

temporary alimentary glycosuria was produced by 100 grams (3 oz.) of glucose; of these four individuals two became diabetic several years later." "In traumatic neurosis or neurasthenia there is often a diminished power of sugar destruction; also Ebstein and Asher have shown that traumatic neurasthenia is sometimes followed by diabetes mellitus." (Williamson's article on Glycosuria in the *Encyclopaedia Medica*.)

Recent Cases.

I have sometimes had under my care women from whom I thought proper to wean their babies, once on account of enterica, at other times on account of some septic condition in the mother. After the weaning the mother's urine would reduce Fehling's solution for several days, the sugar of the milk being absorbed from the breasts into the blood, which, in its turn being surcharged, excreted the superfluous sugar through the kidneys, so that it was found in the urine.

In my own practice, as well as in my own person, I have found reason to be thankful for the new doctrine.

At the South Manchester Poor Law Hospital in 1916 one of my patients was a middle-aged man with a wooden leg. On his first admission, four years before, his bed card was marked "Diabetic Gangrene," and a surgeon had boldly amputated the leg for gangrene, despite his diagnosis of diabetes, as Sir Rickman Godlee would have done. I found the man quite well, and he had no glycosuria, so I had the pleasure of telling him that, according to a great discovery recently made and proved, he had never had diabetes, but only a peculiar and temporary blood poisoning from his bad leg; that I had myself suffered blood poisoning in the same way, only from carbuncle of the neck instead of gangrene of the leg; and that, as regards diabetes, both of us were as found as anyone in Manchester. So he went on his way rejoicing, and I wrote "Sapraemic Glycosuria" on his old bed ticket.

At an epileptic colony the medical officer found Fehling's test for sugar positive in the urine of a young man suffering from a small but angry boil. He asked me, as a puzzle, whether sugar was present or only one of the rare reducing agents described in the textbooks. I diagnosed sapraemic glycosuria, and proved the presence of sugar by the fermentation test. The glycosuria vanished almost as soon as the boil.

A corporal in another war hospital brought me a patient who had been passed in Class A1. I found a large suppurating carbuncle on his neck, and a little glycosuria; no hunger, thirst, emaciation or polyuria. I diagnosed sapraemic glycosuria secondary to carbuncle, and after recovery from both carbuncle and glycosuria, as of my colleagues, but was gentle, would falsify my optimistic prognosis. I soon removed the sloughs, and the glycosuria quickly vanished. Query: If the private had by chance gone to one of my sceptical brethren instead of coming to me, would he have been discharged from the army as a diabetic?

Conclusions.

A. To give our textbooks and teachers their due, we must admit that they used to teach us that there was such a thing as "transient glycosuria." The word "transient," however, was of the lowest practical and scientific value, for on the one hand we could never know that the glycosuria was transient until it was gone, and on the other hand the cause of the glycosuria was left undesignated. But the words "sapraemic glycosuria" have high value: in diagnosis, for the cause is named; in prognosis, because an early, happy result—life instead of death—is soundly predicted; and in treatment, because common diet may be used and the modern starvation and starch-free diet (a great nuisance) is forbidden.

B. I believe that carbuncle or gangrene secondary to diabetes is not very common, but I readily see why so debilitating a disease as diabetes can be, like other forms of debility, a real predisposing cause for carbuncle or gangrene.

(1) In sapraemic glycosuria the sugar is relatively small in quantity. The largest quantity recorded in this paper as having been passed in twenty-four hours is 1,400 grains (or 3 oz.). In diabetes the patient commonly passes from half a pound to three-quarters, say, 4,000 to 6,000 grains daily.

(2) Consequently, in sapraemic glycosuria we find an absence of the great diabetic symptoms—namely, no hunger, no thirst, no emaciation, no polyuria.

(3) In the case of sapraemic glycosuria associated with gangrene there will probably be found enough arterial degeneration in the patient to account for the gangrene without it being necessary to fly to the hypothesis of diabetes.

C. As the sapraemic products of gangrene, carbuncle, erysipelas, etc., differ considerably from each other, it is

"I have recorded here nothing that happened before 1921, but I suspect sapraemic glycosuria in the case recorded by Trube in 1931. 'M. Delpech,' he says, referring to a great French surgeon of a hundred years ago, 'found sugar in a case of carbuncle of lip and chin, which went on to complete recovery.'"

probable that one sapaemia will differ much from another in its power of lowering the saturation point for sugar. At present gangrene and carbuncle are the most striking and misleading agents in the causation of sapaemic glycosuria, but further investigation will doubtless reveal a long series of such agents differing from each other very much in the power of causing sapaemic glycosuria.

SELF-INFLICTED INJURIES IN CIVILIAN PRACTICE.

BY

A. RENDLE SHORT, M.D., B.S., B.Sc., F.R.C.S.,

ASSISTANT SURGEON, BRISTOL ROYAL INFIRMARY:

AND

CYRIL H. WALKER, M.B., F.R.C.S.,

SURGEON, EYE HOSPITAL, AND OPHTHALMIC SURGEON,
GENERAL HOSPITAL, BRISTOL.

I.—MR. RENDLE SHORT.

A CASE like the following might so easily get a surgeon into undeserved trouble that it seems desirable to put it on record.

A young woman, giving her age as 18, was admitted into one of my wards at the Bristol Royal Infirmary in November, 1915, with a three weeks' history of appendicular colic. I removed the appendix. There were two small ulcers in its mucosa. She healed well and went back to her home in the country. On January 27th, 1916, she paid us a visit complaining of pain in the scar, but nothing abnormal could be found.

In December, 1918, she was readmitted, with the history from her doctor that she had been in the workhouse infirmary for many weeks discharging pus and fragments of a gauze swab from the scar of the appendix operation. He and his partner had opened up the wound under an anaesthetic, but could not find any gauze, nor did the track go through the muscles of the abdominal wall. As it still did not heal, and fresh bits of gauze came out, they sent her up to me.

Naturally I was very perturbed. It is an absolute rule with us never to put a swab in the abdomen without a tape and artery forceps on it, to count all swabs before and after operation, and almost never to use gauze packing; but to err is human. The patient's age was now given as 24. For the first few days after arrival her temperature was high, about 103°. At first the pulse was also quick, but after a while the slow pulse, normal general appearance, and very irregular high temperature led us to give her the thermometer again, just after it had registered over 101°, and we found that in the mouth it was normal. After that she was deprived of her hot-water bottle when her temperature was taken, and it became normal.

Meanwhile the abdominal sinus discharged freely. I opened it up on January 16th, 1919, and found no gauze. The tracks were extensive amongst the abdominal muscles, but did not go through them to reach the peritoneum. I cleaned it all up very carefully, and drained the wound after partially closing it. It did not heal. Some weeks afterwards a piece of selvedge-edged gauze came out, such as we never use for swabs. This relieved my mind greatly. She was sent home still with a small sinus and returned to the workhouse infirmary. Mentally she behaved and conversed quite normally. A piece of gauze came out, and in October, 1919, several more pieces of gauze came out, and she became very ill, and

In September, 1919, several more pieces of gauze came out, which were sent me by post. Then she became very ill, and there was a discharge from two openings, one on the abdomen and the other below Poupart's ligament, smelling like faeces. On September 22nd I operated, beginning by exploring the abdomen in the middle line. The abdominal cavity was quite normal. The caecum was not adherent to the anterior abdominal wall, and there was no mass in the right iliac fossa. I closed the abdomen again and slit up the sinuses. There was a foul track connecting them, about six inches long, running deep in the subcutaneous fat but not penetrating the muscles. In the deepest part of the sinus was a piece of wool as large as a haricot bean, with a faecal odour. I thoroughly excised the whole track and sewed up the whole incision in clean tissues. Over the dressing we then put on yards and yards of adhesive plaster, completely encircling the thigh and lower abdomen. The operation was performed in the presence of eight or ten most interested spectators, whose names were recorded in the notes as witnesses.

It was, of course, impossible for the patient to get at the wound, strapped up as it was with continuous adhesive plaster, and it had healed up, though rather insecurely on account of deep sepsis, in about a fortnight. One or two small abscesses formed, discharged, and healed up before we could regard the scar as safe. When she went home, soundly healed at last, I roundly accused her of pushing in the gauze and wool herself. She denied it indignantly.

In January, 1920, so her doctor informed us, the scar started discharging again through a fresh sinus, and presently all her urine was passed through this sinus. She became very ill, and nearly died. In June, 1920, she was readmitted to my ward.

She looked thin and ill. There was a large sinus in the lower end of the old appendix incision, through which the whole of her urine escaped. A skingram was taken, which showed an elongate foreign body lying in the bladder. On June 17th I performed suprapubic cystotomy, and removed a broken piece of a bone knitting needle, four inches long, encrusted with phosphates, which was loose in the cavity of the bladder. When pressed a few weeks after to account for the presence of the needle in the bladder she at first said that her doctor at the workhouse infirmary had lost it in probing the wound, but finally she admitted that she had pushed it into the bladder herself from the abdomen.

When I returned from a holiday at the end of August, though the sinus in the appendix region had healed, the suprapubic opening was still as large as one's finger, and I felt sure that the patient had been tied into the without hastening healing; on one found blocked with wool. Then the end of the catheter disappeared. On August 31st I operated for the fourth time, removed about an inch of the end of the catheter from the bladder, sutured up the suprapubic wound, and secured it with an anchored dressing. To give it a better chance to heal I dilated the urethra sufficiently to give her incontinence for a week or two. By this means the wound eventually healed up, and she was sent out well.

I have recently heard from her doctor (November, 1920) that the suprapubic wound is open again. She makes no secret this time that she did it herself.

It was quite clear to us, from the time of the operation in January, 1919, that these sinuses were the result of self-inflicted injuries, and that the gauze had been pushed in by herself, for the following reasons, quite apart from the routine precautions taken at the original operation in 1915:

1. The original wound healed well, and stayed healed for years.
2. Not one swab, but several small pieces, came out.
3. The sinus did not penetrate the abdominal muscles, so that any swab must have been left, not in the abdomen, but in the abdominal wall, which is scarcely credible.
4. She had already been detected "faking" her temperature.

When later, in spite of two negative explorations of the sinus—one at home and one by me—a piece of selvedge-edged gauze, a lump of wool, and enough separate fragments of gauze to constitute four or five swabs, were found in the track, of course the nature of the case became obvious, and was confirmed by the facts that healing did not take place when she could get at it, but union by first intention took place when she was thoroughly strapped up. Nevertheless, there was a stage when an action at law for negligence in leaving a swab behind would have been all too likely to succeed, and the putting of this case on record may be a protection to some surgeon unjustly accused in the future. Legal proceedings were never threatened against me.

The motive and the state of the patient's mentality are hard to fathom. That she should be an inmate of a hospital and a workhouse infirmary for over two years, and inflict such injuries upon herself as to push a thick bone needle from the right iliac fossa into the bladder, simply to escape work or to excite sympathy (of which she got very little in Bristol), seems hard to believe, yet the only evidence to be found of unsoundness of mind is furnished by these actions. Her behaviour and conversation were otherwise normal.

Perhaps, in view of the incredible nature of the case, it may be as well to state that the facts can be vouched for by a whole succession of my house-surgeons and dressers, and the patient and "finds" have been shown to various surgical meetings. I owe a considerable debt to the acumen of my ward sister, Sister Julia Gross, in clearing up the nature of the case.

One somewhat similar example of a self-inflicted injury has come under my care. Some years ago, when our dermatologist was away at the war, I was asked by the acting out-patient physician, Dr. W. A. Smith, to see a girl, aged about 14, because she got a peculiar rash on her face every Wednesday afternoon at about 1 o'clock. The distribution was that of lupus erythematosus, but the characters were those of irritant dermatitis. Of course the extraordinary time-relation made it quite certain that it was an artefact, though we inquired if there was anything special about her diet on Wednesdays; there was not. I suggested having her up on Wednesday morning

and putting on a lint and ointment face-mask. This was done, and as her mother refused to take her home through the streets like that we had to admit her. On that Wednesday no rash appeared, and she went home next day. On the following Wednesday the rash reappeared, but obviously we could not find a bed for her every week. Why she did it I do not know.

II.—MR. CARL WALKER.

It is not easy to understand the motive which induced the girl whose case is to be related to inflict so much pain upon herself, but I have very little doubt that she was in some way tampering with her eyes long before the pieces of cotton-wool and thread were discovered.

L. G. came to me at the Bristol General Hospital as an out-patient in 1892 when she was 6 years old. She was then suffering from phlyctenular conjunctivitis and keratitis. She soon recovered under the usual treatment, but had very frequent recurrences, so that for some eight or ten years she was almost constantly under treatment. When she was 8 years old she had typical molluscum contagiosum of the eyelids—a disease, by the way, which is seldom seen amongst ophthalmic out-patients now. When she was 12 she developed tuberculous glands in the neck, and in consequence underwent three extensive operations between the ages of 15 and 17. The corneae were at that time so much damaged by recurrent stramonius keratitis that she could only read big print, and no examination of the fundi was possible. When she was 18 she had an extremely severe and intractable attack of keratitis affecting both eyes, and accompanied by great photophobia and intense spasm of the orbicularis. She was an in-patient for some months, and towards the end of her stay in hospital it was noticed that on two or three occasions a tiny piece of cotton-wool or of thread from a bandage was found in the conjunctival sac. She was not definitely accused of having introduced these foreign bodies, but she was questioned about it and told to be very careful not to touch her eyes herself. Her general condition slowly improved, and her eyes gradually quieted down. The corneae had been rendered very opaque all over by the interstitial keratitis. No fundus reflex could be obtained, and her vision was reduced to bare perception of light. The corneal condition was not enough to account for such great loss of sight, and it must be assumed that she had choroiditis at the same time as the keratitis.

Soon after this, as her health was fairly good and there seemed to be no further prospect of recovery of sight, she was admitted to the Blind Asylum as a resident pupil. Attacks of conjunctivitis with keratitis soon came on, and after several attacks Dr. Flemming found that she deliberately introduced pieces of the thick paper used for Braille writing under her lids. On three occasions a piece as large as the finger nail was found in her right eye. She was very sternly spoken to by Mr. Cross, and an exaggerated account of the risk she ran of setting up dangerous, perhaps fatal, inflammation induced her to desist from any such pranks again. Since then she has had no similar attacks.

Such practices amongst ophthalmic patients have often been recorded, but usually the immediate object is obvious—to excite sympathy, to prevent returning to work, or to gain admission to hospital. I recall the case of a young woman who was much crippled with arthritis, and who, besides attending at the electrical department, repeatedly for some years came to my ophthalmic out-patients with "conjunctivitis" which was never at all severe and left no trace. It always got well quickly with boric lotion and mild astringents. On one occasion, as she was leaving the consulting-room, she dropped a small piece of hard dry white soap. She picked it up hastily, but not before I had seen it. On being asked what it was for she made no reply, but turned very red. She had no more conjunctivitis after that day, though I often passed her on her way to and from the electrical department. The inference is almost irresistible that the conjunctivitis was self-inflicted, and that the soap was the agent used.

NOTES ON ONE THOUSAND CASES OF BILHARZIASIS TREATED BY ANTIMONY TARTRATE.

BY

I. O. LASBREY, M.B., AND R. B. COLEMAN, M.B.,
CH B. CH B.

PRINCIPAL AND ASSISTANT MEDICAL OFFICERS, CHURCH MISSIONARY
SOCIETY'S HOSPITAL, OLD CAIRO, EGYPT.

Of a reason for adding still another chapter to the rather numerous articles written on the subject of the treatment of bilharziasis by intravenous injections of antimony tartrate is the fact that up to the present time the con-

clusions arrived at have been based on the investigation of a comparatively small amount of clinical material, whereas we have been able to avail ourselves of the exceptional opportunities which Egypt affords for making observations on very large numbers of patients.

We can add little fresh information to what has been noted in previous articles on the subject, but with the records before us of 1,000 individuals who have undergone treatment at our hands, we are able to verify what has already been written on the subject, and venture to think that our testimony to the efficacy of the antimony tartrate treatment may be of some value, and a report of the results of the treatment of our first thousand cases of general interest.

Since June, 1919, injections of antimony tartrate in accordance with Dr. Christopherson's observations have been the routine treatment for bilharziasis at the Church Missionary Society's Hospital, Old Cairo, and we are now injecting from fifty to seventy cases a day; both urinary and rectal bilharziasis are being treated, but the former in a much larger proportion.

Dose.

In cases without contraindication the usual method has been to start with 1 grain as the initial dose, increasing by 1 grain at each injection, so that the maximum of 2.5 grains is reached at the fourth injection; this dose is then repeated at all subsequent injections. Injections are given on consecutive days for the first six days, and then on alternate days. The dose is altered in the following cases: Weak men and most women take slightly smaller doses. Children take much smaller doses in proportion to their size and condition. All cases showing much reaction—for example, fever, loss of appetite, etc.—are given smaller doses, and some are given longer periods between injections. It is worth while mentioning that the liberal dosage mentioned above is found necessary in order to cure the disease within a limited period. Our patients, most of them farm labourers, are unwilling to prolong their stay in hospital unduly. On the other hand, it appears that a much smaller and more gradual administration of antimony is equally effective. Quite small doses spread over a considerably longer period appear to cure the disease, the main point being the cumulative effect of about 20 grains of the drug.

Examination.

All cases are submitted to microscopical examination before beginning the course. A re-examination is made after the sixth dose, and subsequently after every dose, and a daily report made with regard to the presence of bilharzia eggs, their condition, and the relative proportion between dead and living eggs in each specimen. When all eggs are found "dead" injections are stopped. The urine is examined again on the two following days, and on three consecutive reports of all eggs being dead the patient is considered free from bilharzial infection. Unfortunately some patients after one report of "all dead" will not stay for further examination. Examinations are made as follows: The urine is allowed to stand for a quarter of an hour, and the deposit pipetted off for examination. If the result is negative the lower layer of the urine in the specimen glass is centrifuged and the deposit examined. Dead eggs are shrivelled and black. No organism is visible in the eggs, and they fail to hatch out on the addition of water.

Rectal cases are more difficult to pronounce free from bilharzial infection, for sometimes eggs do not show for days together. Consequently in these cases we do not usually depend on microscopical examination, but give the full course of twelve doses, amounting to 27 grains of antimony tartrate.

Statistics.

In 1919 (June to December) 370 cases of bilharzial disease were treated, while in 1920 (January to August) our books record 630 cases. Proper records of the first 150 cases in 1919 were not kept, and of the remaining 220 we find that 44, or 20 per cent. of the total number, received less than six injections each. This is not surprising considering that the antimony method of treatment is by no means free from discomfort. Moreover, treatment was abandoned in the case of a few where adverse symptoms, such as marked debility, anorexia, etc., supervened after a

few injections. It may be remarked, however, that many of those who took only a few injections experienced remarkable alleviation of symptoms. Of the remaining 176 cases:

24 had 7 to 9 doses, totalling an average amount of 18 grains.
92 had 10 to 12 doses, totalling an average amount of 25 grains.

Of these, 81 were pronounced cured by the above tests, the majority of them having taken the larger number of doses, that is, an average amount of 25 grains. This means that 81 individuals, or 42 per cent., were proved cured out of 176 who more or less completed the course of treatment. Almost without exception those not pronounced cured were benefited to a very large extent, and the examinations showed a large proportion of dead eggs, but it is not our method to call them "cured" so long as any living eggs appear, or even in the event of no eggs at all being seen. Dr. Christopherson emphasizes this latter point, and we agree strongly as to its importance. Again, the very marked relief of symptoms which many experience is in itself a cause of a certain percentage of patients not persevering in the treatment after the haematuria and general distress have disappeared; thinking themselves cured, they choose to leave hospital without waiting for an examination, or in spite of the fact that living eggs are still demonstrable in the urine.

By 1920 the antimony method had passed the tentative stage, and patients were beginning to seek treatment with greater confidence; consequently the 1920 records show an increasing number of cases and a higher percentage of cures.

Of the 630 cases treated between January and August, 1920, 20.6 per cent. did not take as many as six doses, the continuance of the treatment being contraindicated in a few, while the rest did not persevere. Of the remaining 500:

13 had 6 doses, amounting to	12 grains
57 had 7 " " " " " "	...	14.5 "
55 had 8 " " " " " "	...	17 "
138 had 9 " " " " " "	...	19.5 "
107 had 10 " " " " " "	...	22 "
70 had 11 " " " " " "	...	24.5 "
59 had 12 or more doses, amounting to	27 "

Of these 500 we find 348 were pronounced "cured" according to the above definition—that is, nearly 70 per cent. The increase in the proportion cured over the first series is not due to any difference in the treatment or its results, but mainly to the course becoming more popular, and the consequent willingness of a greater number of patients to wait for its conclusion. As far as our experience goes, we find that all cases strong enough to take the treatment become cured if they continue with it; this year's series produced more "cured" with a slightly smaller dose. The desired result being most frequently obtained after nine, ten, or eleven doses, as follows:

After 9 doses 97 were "cured."
After 10 doses 79 were "cured."
After 11 doses 61 were "cured."

These amount to just 70 per cent. of the total number of cured, and this means that the usually effective dose is from 19.5 to 24 grains, and exactly bears out Christopherson's opinion that the dose of antimony tartrate required for an adult is between 20 and 30 grains, and that it is generally nearer 20 than 30 grains.

Mortality.

In the total series of 1,000 cases we had 10 deaths which could in any way be attributed to the treatment or to the disease itself, a proportion of 1 per cent. Six deaths occurred in the first series of 370 patients, and only 4 in the second series of 630 cases. Thus the percentage during 1920 has been considerably reduced. We regard this as very satisfactory when the poor condition of so many of the patients is considered. Not a few of those who apply for treatment are in a very miserable state. In some the kidneys are affected, and the urine shows a very low specific gravity. Eager to grasp at any possibility of cure, it is only fair to give these physical wrecks the chance of recovery. If they stand the injections well these are continued; if they develop bad symptoms the course is abandoned. We attribute the lessened mortality in 1920 to a greater watchfulness and caution in weeding out patients exhibiting marked intolerance for the drug, to more gradual administration, and to a great moderation of dosage in very feeble subjects.

The usual symptoms preceding death are total loss of appetite, extreme debility, and complete apathy. The patient curls up in bed and lives perhaps for some days before the fatal issue. Then a sudden effort, such as rising from bed, is followed by fatal syncope. No death took place immediately after an injection, and usually some days supervened between the last injection administered and the fatal issue. The total amount of antimony administered in several of these cases was very small.

Technique.

As we have to deal with a very large number of cases, it is important that the routine should be as simple as possible and the work reduced to a minimum; this department has been added to the already heavy daily round of a large hospital with all its varied medical and surgical work, without any addition to the staff. An Egyptian orderly has been trained to do all the microscopic work, and all cases are examined by him before beginning the course and again after the sixth and every subsequent injection. He sends in his reports daily to the sister in charge of the section. The latter supplies every patient with a card on which is marked his name, number, and the date and amount of each dose; all this is also noted in her book of records together with notes concerning the presence in the urine of bilharzia eggs, blood, pus, the urinary specific gravity, etc. Each morning, before the arrival of the doctor, she marks all the cards for that day and the patients are lined up. Any doubtful cases are reserved for further inspection. The antimony tartrate is supplied in tablets for solution, especially made by Messrs. Parke, Davis and Co., containing 10 grains each. From these a sterile solution is made containing 1 grain in 20 minims. This is dropped from a drop bottle into a sterile cup and further diluted to make up about 10 c.cm., which is then ready to be drawn up into the syringe. A 10 c.cm. glass syringe is used, with two or three needles. All the apparatus is boiled before commencing work. After each injection sterile water is drawn up into the syringe, which is then rinsed out and the needle is removed and immersed in a glass of rectified spirit.

The patient holds up his record card, the sister measures out the doses indicated thereon, and the doctor draws up the solution into the cleansed syringe and adjusts a needle. The patient sits on a chair with his arm extended on a table and his fist clenched. An Egyptian orderly firmly compresses the upper arm with one hand and strokes up the forearm with the other; he paints iodine on the bend of the elbow, and the doctor injects into a prominent vein, the orderly releasing his pressure, and the patient opening his hand. After injection no bandage or dressing is used, but the patient holds his arm up for about five minutes. In this way we inject patients daily at the rate of more than sixty an hour. Occasionally some patients, more especially women and children, have very indistinct veins, and in such cases some trouble is experienced now and again in finding the lumen of the vessel, but fortunately these are few in number. Great care is taken not to let any fluid escape into the tissues. Should this accident occur, the patient feels it at once and says so. If only a drop or two escapes a painful arm results, necessitating the application of fomentations, etc. In the early months we had several such mishaps, one or two causing local abscesses, but now with increased practice we very rarely get any trouble at all.

It has been questioned whether our sterilization is sufficient, especially in that we do not boil the syringe after each injection; but taking into consideration the nature of the fluid injected and the immersion of the needles in spirit before each operation, the method is regarded as adequate. Moreover, in the whole series no case has exhibited the slightest sign of sepsis from faulty sterilization.

Accommodation for Patients.

The majority of those taking the antimony course are in-patients, some of them occupying beds, but the larger number lying on mats in our large open-air "anaemia pavilions." The reason for this is that most of them also suffer from ankylostomiasis, and are being treated for that ailment at the same time. The injections are not begun until two days have elapsed after the patient's first dose of chenopodium oil or thymol with the accompanying fasting, etc., and likewise they have a few days' rest before the

subsequent doses of these parasitocides. A considerable number, however, take the antimony course as out-patients, attending hospital regularly for their injections.

Complications.

Many patients have complications due to the disease, which are appropriately dealt with. Vesical calculus is treated by lithotomy or suprapubic cystotomy, the injections being continued. Bilharzial growths of the perineum, often resulting in urinary fistulae, are treated by operation in addition to injections. It is remarkable to notice the influence of the injections on the healing of these fistulae: down to a year ago they used to be our most chronic cases, often taking months to heal up after operation. Now the average case heals in about twenty days. Rectal cases showing friable, cauliflower tumours of the mucous membrane, many of considerable size, are treated by ligature, and in the case of small growths by removing as much as possible by scraping with the finger-nail and swabbing with zinc chloride solution. Again, the influence of the injections on these growths is very marked, as many of them quite disappear in a comparatively short time after scraping. Previously two or three operations were necessary. As regards other complicating conditions a very large proportion of the cases, as mentioned above, also suffer from ankylostomiasis, and a considerable number have pellagra. Nephritis is observed occasionally, and in several weak patients with this complication the treatment had to be abandoned.

Late Results.

In a country like Egypt it is always very difficult to follow up cases and to get satisfactory statistics, but we have inspected several patients some months after treatment who testify to the complete relief of all symptoms. Microscopical examination, moreover, still shows only "dead" eggs. The same result is found in several of our own workers who took the course a year ago. In no case have we seen living eggs reappear after completing a successful course, though obviously this might be possible owing to reinfection.

CONCLUSIONS.

1. The results of the antimony treatment on a large scale bear out in a remarkable way the findings of those who have recently written on the subject, and especially of Christopherson, to whose original research is due the fact that bilharziasis need no longer be regarded as an incurable ailment.

2. As most ordinary patients are unwilling or unable to make a protracted stay in hospital, it is necessary to hasten the antimony course and thus give liberal doses; yet in cases where it is possible we urge a more gradual administration of the drug, and in this way we believe risk will be reduced to a minimum, while the eventual cure will be as surely effected; 20 to 25 grains of antimony tartrate is, in our experience, the average amount required to effect a cure. While a less toxic substance than antimony tartrate would be welcomed, we are persuaded that its toxic effects can be largely eliminated by cautious administration.

3. To reduce the mortality a very careful investigation of cases is necessary. "Rests" should be given on the occurrence of any untoward symptoms, the dose lessened at the least indication, and the course immediately abandoned in cases showing marked intolerance.

4. The above technique is recommended as being simple and rapid where large numbers of patients are to be dealt with, as, for instance, when any attempt is made to eradicate the disease in infected districts.

5. It is noteworthy that the successful surgical treatment of complications dependent on bilharziasis, such as urinary fistulae and rectal papillomata, is enormously facilitated by the elimination of the causative factor.

THE third annual meeting of the Board of Governors of the League of Red Cross Societies will be held in Geneva on March 28th. The Board contains representatives of the Red Cross of the United States, Great Britain, Australia, France, Italy, Japan, Spain, Sweden, Brazil, Switzerland, Argentina, Belgium, Denmark, and Serbia. The chairman is Mr. Henry P. Davison, of the American Red Cross, and the vice-chairman the Director of the League, Sir David Henderson.

STENOSIS AT THE INTERNAL MEATUS AFTER SUPRAPUBIC PROSTATECTOMY.

BY
ANDREW FULLERTON, C.B., C.M.G., M.Ch.,
F.R.C.S.I.

SURGEON, ROYAL VICTORIA HOSPITAL, BELFAST.

ALTHOUGH Freyer's operation of suprapubic prostatectomy, correctly performed, is rarely followed by serious after-effects, a recent article by Thomson Walker¹ shows that stenosis at the vesico-prostatic orifice is not a very uncommon occurrence. In a certain proportion of cases after prostatectomy it is difficult or impossible to pass a catheter into the cavity of the bladder, even when the patient does not complain of any difficulty in micturition. The instrument hitches against a diaphragm roofing the remains of the cavity once occupied by the prostate. The point of the instrument can be moved more or less freely in a space in front of the rectum and behind the bladder, and the injection of fluid, unless very slowly performed, is apt to give rise to pain. The fluid, however, if slowly injected, may find its way into the bladder. The difficulty in introducing the catheter is due, first, to the absence of the guidance of the prostatic urethra, and, second, to the fact that the vesical orifice of the prostatic cavity is not in alignment with the direction of the urethra. It is, in fact, difficult to hit off with the point of the catheter the vesico-prostatic opening. If, in addition, this opening has contracted, the difficulties are much increased. (See n, in diagram).

A, Vesico-prostatic septum.
B, Stenosis of vesical orifice.
C, Prostatic cavity.

The following are illustrative cases:

CASE I.

In July, 1914, I removed an enlarged prostate and a villous growth in a patient aged 70 years. In November of the same year he returned, as directed, for cystoscopic examination to ascertain if any recurrence of the villous growth had taken place. I found it impossible to introduce the cystoscope, though the patient denied any difficulty in micturition. After trying several catheters and dilators I was able to pass a small instrument and to dilate gradually the internal opening sufficiently to admit the cystoscope and destroy with the high frequency current a commencing papilloma. In December of the same year I again had difficulty in dilating him sufficiently to pass the cystoscope. In September, 1915, I passed the cystoscope once more, and again destroyed a small papillomatous bud. Immediately after this I went abroad and did not see the patient again, but I ascertained that he remained well until his death from apoplexy in September, 1919, at the age of 75.

CASE II.

In April, 1919, I removed an enlarged prostate in a patient aged 61 years. Fourteen days after his operation he could hold his water for six hours and pass it in a vigorous stream. In May the suprapubic wound began to leak, and I attempted to pass an instrument into the bladder, but only succeeded in getting in a fine catheter. The wound healed in a few days and remained firm until June, when it again leaked for a few days. I saw him subsequently for cystitis, and tried to pass a catheter to wash out his bladder, but failed absolutely. As his symptoms were slight he refused to have anything further done. I have seen him several times since, and he informs me that he is passing water freely and without pain.

CASE III.

A third case gave me a good deal of trouble. The patient was aged 64 years. I removed his prostate in May, 1919. He passed urine on the twenty-sixth day, but leaked a little from the suprapubic wound on micturition for a fortnight after. From this on his wound was dry, and he left the nursing home apparently well on the road to recovery. It was evident, however, as time went on that he had not obtained the usual relief from prostatectomy. He complained of frequency and pain, passing small quantities of water at a time with much difficulty and straining. The urine contained a good deal of pus. In March, 1920, an attempt was made to pass an instrument to wash out his bladder. All kinds and shapes of catheters and dilators were used, but none of them could be got to enter the bladder. Fluid injected at the meatus was tolerated, and disappeared, presumably into the bladder. On March 19th, 1920, cystotomy was performed through the suprapubic scar. The bladder was empty. The prostatic cavity was roofed over by a

membrane in which could be felt and seen a small umbilicated opening in the middle line anteriorly, admitting an ordinary probe (see in diagram). The prostatic tent-like roof was slit from before back in the middle line. As the incision was prolonged backwards it was found that the septum became thicker as it passed back to become continuous with the bladder wall. When the operation was completed there was a deep and wide sulcus bisecting the base of the bladder and throwing the prostatic and vesical cavities into one. A drain was inserted and the bladder irrigated daily. On April 2nd the wound was dry, and the patient was able to pass water in a good stream. On May 7th a full-sized dilator passed easily into the bladder.

In order to avoid this complication I have recently taken the precaution of slitting posteriorly with scissors the vesico-prostatic septum as far as its junction with the bladder wall immediately after removal of the prostate. This step is facilitated by grasping the margin of the septum on each side of the middle line with Lane's tissue forceps and cutting between. If the line of incision is clamped by pressure forceps before cutting, bleeding is avoided.

It might be desirable to pass full-sized dilators at intervals for a time in cases in which this complication is suspected and has not been provided for at the primary operation. Thomson Walker, in the article referred to, draws attention to this obstruction, and describes a method of dealing with it. He also extends the operation of Freyer to prevent its occurrence by removing a wedge with the base forwards, from the posterior lip of the prostatic-vesical opening.

I am indebted to Mr. R. H. Hunter for the accompanying diagram.

MEDICAL, SURGICAL, OBSTETRICAL.

HERPES AND VARICELLA.

The following series of cases apparently proves that varicella can be contracted from a patient suffering from herpes, and vice versa.

Just before Christmas a school child was brought to me suffering from herpes on the thigh and buttock. On January 10th and following days several cases of varicella occurred in the village among school children.

On January 17th I was called to see a man aged 35 with supraorbital herpes. Several other children went sick with varicella about February 1st.

On February 10th I saw a man with occipital herpes. There was another batch of children down with varicella on February 14th, and this morning (February 19th) yet another man came to the surgery with supraorbital herpes.

So far as I can make out none of the patients with herpes can have contracted it directly from either of the other patients with herpes, and varicella has apparently acted as a connecting link between them.

The population of the village is only about 1,000, so the occurrence of four cases of herpes at about the same time is unlikely unless it is to some degree infectious.

Stokenchurch, Bucks.

E. L. ELLIOTT, M.B., B.S. Lond.

CONCURRENT HERPES ZOSTER AND
VARICELLA.

On November 10th, 1920, I was asked to see, in consultation, a medical student, aged 22 years, who was suffering from herpes involving the upper branches of the right fifth cranial nerve. The history of the case was that on October 31st he began to suffer from intense neuralgic pain in the right side of the forehead and scalp and in the right eye. On November 6th herpetic vesicles appeared on the forehead and scalp over the skin area supplied by the ophthalmic division of the right fifth cranial nerve, and the pain was now so severe as to prevent him from sleeping, and at the same time evidently much diminishing his self-control. I ordered him some butyl-chloral hydrate as a sedative, and, seeing him again the following day, found that herpetic vesicles had appeared on the skin supplied by the same division of the fifth left cranial nerve. On

November 12th, that is, six days after the initial herpetic eruption, a generalized varicellar eruption came out on the trunk, upper and lower limbs. There was no pain from the new eruption, and it disappeared in about six days, leaving no scars, whilst the initial vesicles took a further fourteen days to heal, leaving extensive scarring of the right side of the forehead.

ROWLAND HILL, M.D., M.R.C.P. Lond.,

Assistant Physician, Belfast Hospital for Sick Children.

TREATMENT OF LOCAL LEISHMANIASIS.

With regard to Colonel Erskine Risk's treatment of Delhi boils with solid caustic potash, noted in the *JOURNAL* for February 19th, p. 267, I may state that I have used Loeffler's methylene blue with favourable results in this affection. Loeffler's methylene blue has a small quantity of caustic potash (KOH) in it, and I suppose this ingredient was the curative agent. Painting this blue solution over the sores twice a day proved efficacious in a week. The use of solid caustic potash on the face anywhere near the eye might be fraught with discomfort if not with danger.

C. DONOVAN,

Lieut.-Colonel I.M.S. (ret.).

Faringdon, Berks.

A BULLET IN THE CAUDA EQUINA.

The following case seems worthy of record because of the site of injury, the safe removal of a foreign body from such a delicate situation, and the comparatively slight symptoms produced during a period of five years.

Pensioner E. was admitted to the Ministry of Pensions Hospital, Neath, with a history of a gunshot wound of the left buttock. He complained of swelling in the feet, with numbness and inability to bend down owing to pain in the back. His history showed that in April, 1915, he received a wound in the buttock while in charge of a party leaving a front line trench, and he fell over some barbed wire, his legs having "given way." He remained there some hours before being moved to the casualty clearing station. From there he was sent to Bethune and later to Boulogne, where, he states, he was unconscious for several days. On recovery he was sent to England "suffering severely in the back," and in due course he was discharged as unfit in September, 1915. From this time to 1917 he was able to get about fairly well walking with sticks, but with occasional attacks of pain and numbness, especially in the left leg. Late in 1917 he commenced light work which he continued until admitted to this hospital in October, 1920. A ray revealed a foreign body lying in or around the spinal canal, at the level of the interspace between the third and fourth lumbar vertebrae, and at an approximate depth of 2 in. from the skin. As the pressure symptoms were becoming more marked Major Alwyn-Smith, D.S.O., F.R.C.S., visiting orthopaedic surgeon, decided to operate. When the spines of the third and fourth lumbar vertebrae were removed dense scar tissue was found around the laminae. The latter were removed very carefully by chisel owing to the depth of the wound and its limited extent, and haemorrhage, at times free, was controlled by packs of adrenalin. The dura mater now exposed was found thickened by an annular mass of scar tissue, which was dissected off and the dura incised. A small quantity of cerebrospinal fluid escaped, necessitating rapid elevation of the foot of the operating table. On palpation the cauda equina was found to be hard, and had a resistant feeling which was evidently due to some foreign body lying within. Further cautious dissection revealed a bullet lying longitudinally, apex upwards, embedded in scar tissue. This foreign body was removed from the cauda equina, the dura stitched, and the operation completed. No untoward symptoms or signs arose, and the wound healed rapidly. In a few days a plaster spinal jacket was applied, and this was worn for six weeks. The patient was discharged well, with all movements normal, and with no loss of sensation.

I am indebted to Major Howard, medical superintendent, for permission to publish this case.

D. H. VICKERY,

Senior R.M.O., Ministry of Pensions Hospital, Neath, Glam.

It was reported to the London County Council on February 8th that during the three months ending with September last 360 samples of milk from twenty-four English counties were taken at London railway stations. Of 15 (or 4.16 per cent.) proved to be tuberculous. Of 608 cows at twelve farms situated outside the county of London which were examined by the Council's veterinary inspector, 13 were found to be affected with generalized tuberculosis. The usual arrangements were made with the farmers for the disposal of these animals.

Reports of Societies.

SKIN DISEASE: ITS RELATION TO INTERNAL DISORDER.

A DISCUSSION on skin disease in its relation to internal disorder took place at the Medical Society of London on February 14th. Sir F. W. Mott presided.

Sir JAMES GALLOWAY, in the course of his opening paper, spoke in the first place of the erythema group of cutaneous affections. The special eruptions of the acute exanthematous diseases seemed most probably to result from the direct action of the infecting elements, protozoal or bacterial, on the skin. The considerations which led to this conclusion were the distinctive character of the eruptions in each disease, and the fact that in certain of the diseases the organism recognized as the cause of the disease had actually been found in the exanthem. Special opportunities had arisen for the careful study of erythematous reactions as a result of the use of alien antitoxic serums in the treatment of certain of the infective fevers. Variations from the normal reaction occurred, due to what was apparently the increased or the diminished reactivity to the action of the alien protein. Two facts stood out clearly for recognition from the clinical point of view: (1) as a result of absorption of proteins alien to the invaded organism, eruptions made their appearance closely similar to the erythema group of skin diseases; (2) these eruptions varied in degree, severity, and time of incidence, the variations depending on stages of increased or diminished sensibility which might be acquired by artificial methods. The speaker then dealt in particular with erythema exudativum. His conclusion was that general or focal infections were capable of admitting toxins into the body which produced destructive influences, and also that substances resembling more closely the alien proteins producing the protein reactions—serum sickness and analogous conditions—might find their way into the circulation in visceral disease. Erythema nodosum he thought might be a "true" eruption, the manifestation of a specific circulating poison producing local damage, just as the special eruptions of the specific fevers. Lupus erythematosus was thought by some to be caused by the absorption of toxins from chronic tuberculous foci, though the disease occurred sometimes in its most widespread and dangerous manifestations where there was no evidence or suspicion of tuberculosis in the ordinary sense. In herpes gestationis he thought it fair to assume that the embryonal cells and their products might act as an alien protein. Diseases of the skin associated with functional disturbance of the blood vessels required much further observation before their causes could be understood, though disease of the blood vessels causing obstruction to the supply or return of the blood produced more easily understood changes from malnutrition, secondary pyogenic infection, and necrosis. The nervous system, both central and peripheral, had long been held responsible for influencing disease of the skin, but it was not easy to trace the actual influence, even when it might be strongly suspected in individual cases. The most interesting instance of close relationship was in herpes zoster, which had directly to do with a peculiar, often haemorrhagic, inflammation of the posterior root of the ganglia of the spinal cord and the analogous ganglionic structures, but the series of cutaneous reactions and injuries associated with disease of the spinal cord and brain were not so easy of explanation. Finally, Sir James Galloway dealt with the relationship of the skin to disorders of the abdominal and other viscera. He spoke of it as a matter of surprise, considering the close physiological relationship between the kidneys and the skin, that disease of the kidney was not more often accompanied by skin manifestations. There were very few examples of skin outbursts occurring in the course of "Bright's disease." It was not infrequent to find a record of albuminuria, haematuria, and nephritis in cases of erythema multiforme; but the presumption in such cases was that the cutaneous disease and the renal disorder were manifestations of the same toxic cause. Many remarkable manifestations on the skin occurred during the course of disorders of metabolism. It seemed that in glycosuria and allied conditions substances derived from

the imperfect metabolism of the fats might be deposited at certain vulnerable points in the body, and by their presence produce local irritation and multiplication of the connective tissue cells; or, on the other hand, that poisons due to metabolic errors might damage these areas, and that the lipid substances were formed locally in consequence, and aided in the production of the characteristic nodule in, for example, xanthoma. Lichen planus seemed to occur with undue facility in persons suffering from glycosuria and allied disorders of nutrition. Sir James Galloway concluded with a reference to lymphatic leukaemia and to Hodgkin's disease, in both of which similar phenomena affected the skin, taking the form in both cases either of tumours or of remarkable pruriginous reactions without definite tumour formation. The evidence seemed to point strongly in both cases to the infective origin of the classes of disease of which these two conditions were examples.

Dr. ARTHUR HALL (Sheffield) dealt with the functions of the skin as a surface organ, which, he said, except as a heat-regulating mechanism, played no obvious part in the general metabolism of the internal organs. The importance of the relation to the skin of things outside the body quite outweighed the importance of the relation of the skin to the domestic functions of the body; the skin was a coastguard rather than a part of the merchant service. If the individuality of the skin as an organ were kept in mind, greater progress in knowledge would be made than if the skin were regarded as a kind of screen upon which the clinician could view what was going on in the organs beneath. He believed that many changes in the skin now attributed to internal disorders were capable of explanation as natural reactions of the skin to definite stimuli, and though there were many skin affections which obviously were due to internal disorders—the rashes of the exanthemata, for instance—even there the individuality of the skin could not be overlooked. A list of so called skin diseases due to changes within the body could easily be drawn up, and would not be very long; a similar list of affections due to causes from without would be longer, but a considerable list of skin diseases would still remain unclassified, and these would include many common affections, amongst them many of the conditions once called eczema. In trying to ascertain the truth with regard to these, the part which the skin itself played must always be borne in mind. It was often noticed that a patient who was being treated for some trivial local eruption suddenly developed a widespread acute weeping dermatitis; this followed usually from the application of some new material to the skin, often of apparently harmless character. In his view, the acute outbreak did not depend solely upon the material applied, but upon the susceptibility of the individual—upon his neuro-cutaneous reaction to that particular material. Such irritants as primula or phenylhydrazin were not universally irritating; most people could handle them with safety, yet in those whose skins were susceptible the violence and extent of the reaction went far beyond the duration or extent of contact. He gave a history of an interesting case in point. This type of skin reaction to some particular substance was more common than was thought, and there was something more about it than the anaphylactic phenomenon. But our knowledge of the defensive reactions of the skin was not yet sufficient to permit of very definite conclusions.

Dr. E. W. GOODALL took up the question of anaphylaxis. There were some, he said, who held that an attack of an acute infectious disease was an anaphylactic reaction; in his own view an attack of an acute infectious disease was neither an anaphylactic phenomenon, nor was it brought about in exactly the same way as an attack of serum sickness. The symptoms of an acute specific infectious disease were due to two main causes—a special toxin and the common protein cleavage product.

Dr. E. GRAHAM LITTLE referred in particular to lupus erythematosus. He was reluctant to accept a tuberculous causation of this disease, chiefly on the ground of what he had seen in children. He had never seen any evidence of this association among the patients in a large children's hospital, where many tuberculous children were received.

Dr. H. W. BARBER agreed with Dr. Graham Little in thinking that there was no definite evidence of tuberculous causation of lupus erythematosus. Certain cases exhibited stigmata which were supposed to indicate—and probably did indicate—an infection with tubercle in early life, and

cases had been published in which the acute form of lupus erythematosus had been associated with active phthisis or even general tuberculosis. But, speaking of his own cases, in not a single one had he found any evidence of active tubercle. In all his cases he had recovered the virulent long-chain streptococcus, sometimes in pure culture. The primary foci were usually the teeth or tonsils, sometimes the nasal sinuses. There was a very close relationship between lupus erythematosus and rheumatoid arthritis.

Dr. H. G. ADAMSON said that a great many skin diseases which were formerly supposed to be due to internal disorders were now discovered to be the result of external causes entirely. Even scabies and ringworm were at one time thought to have an internal cause. Not all skin diseases were external in origin, of course; some were due to micro-organisms brought to the skin by the blood stream from internal affections, as in syphilis and the specific fevers, and others were due to toxins similarly brought. But for the most part, the cause of the skin condition was the cause of the bodily disorder; the rash of measles, for example, was due to the micro-organism which caused measles, and not to the disease itself.

Dr. J. M. H. MACLEOD thought that the help of the physiological chemist would have to be enlisted more and more in endeavouring to trace these subtle foreign proteins or antibodies that were responsible for one or other toxic rash. It seemed to him that just as the skin was an important and essential organ of the body, linked up directly or indirectly in its perfect function with every other organ, so any diseased condition of any other organ, if it went on long enough, was liable to be associated with a disorder of the skin; and, on the other hand, any diseased condition of the skin, however local its etiology, was liable to be influenced more or less profoundly by the general internal state.

Dr. H. MACCORMAC said that it was not always realized that even local skin affections might also depend upon some general condition. Even in ringworm of the hair of the scalp, the process died out spontaneously at puberty, so that there was evidence of some change in the tissues caused by some condition of which they could have no microscopic or other evidence. He referred also to a vitamine-deficiency disease from which the Eskimos suffered during the absence of fresh seal meat from their diet; it consisted of an eruption in various parts of the body, pustular in type, and very irritating, but disappearing when the food supply became normal. There one got a pustular infection of the skin which could only arise from a profound change in the tissues.

Sir F. W. MOTT, in closing the meeting, said that the question of anaphylaxis was one on which he would have liked to have spoken, but for the lateness of the hour. The French looked upon this phenomenon as "a dislocation of the static equilibrium of the colloids."

TREATMENT BY X RAYS AND RADIUM.

At a meeting of the Edinburgh Medico-Chirurgical Society on February 2nd, Emeritus Professor F. M. CAIRD presiding, Dr. R. KNOX (London) opened a discussion on treatment by x rays and radium. After dealing with physical data, the technique of application, the measurement of doses, etc., he discussed the results of radiation treatment in clinical conditions. Superficial lesions of the skin were the earliest to be treated, and remained still the most favourable in results. It was the best treatment for tinea capitis, though permanent baldness resulted in a few cases. In rodent ulcer radium was better than x rays, which perhaps explained the lesser frequency of relapse in later cases. Most of the early cases did well at first, but sooner or later relapsed, and then resisted radiation. Lupus vulgaris sometimes gave good results, but here regulation of doses was necessary to avoid the real danger of lupous carcinoma. Hyperidrosis was readily controlled. The blood and body fluids were profoundly affected by radium and x rays. In leukaemia the immediate effect was striking, in reduction of the spleen and of the leucocyte count; but though the disease might be controlled for years, the final result was nearly always relapse. In this disease, as in Banti's disease, radium was better than x rays. In exophthalmic goitre radium should be given at the bedside, but combined with rest and

drugs. In conditions of lymphatic glands, simple inflammation and lymphadenoma rapidly responded; so also sarcoma, but with later relapse; with tubercle and carcinoma the response was slow. In fibromyomata of the uterus the tumours never disappeared; they were often reduced by a third or a half, and even where the reduction was not appreciable there might be great improvement in health from the cessation of haemorrhage and from effects upon ovaries and blood. A proportion of these cases were not benefited by radiation treatment. In carcinoma of the breast he advised a preliminary radiation before operation, and after it thorough treatment of the operation and drainage areas. Some of the cases of early recurrence were also amenable, while certain inoperable cases after x-ray treatment became operable. Other benefits in bad cases were the healing of ulcerated areas and the relief of pain. In uterine cancer a combination of local radium treatment and of x rays applied externally was advised. He concluded by forecasting an early improvement in technique, enabling x rays of greater penetrative power to be used, and by pleading for closer co-operation between the clinician and the radiologist.

Professor ALEXIS THOMSON gave some personal experiences with radium in malignant tumours. It could not be trusted alone, and even when there was an apparent disappearance of the tumour he advised operation. Also relapsing tumours seemed to be immune to radium action. A good rule was in operable tumours to operate and insert radium, and in inoperable tumours to attempt to render them operable by radium. Of the sarcomata, the lymphosarcoma was most amenable to treatment. Dr. CRANSTON Low said that x rays had revolutionized the treatment of ringworm; only 1 per cent. of the cases developed permanent alopecia; by its means ringworm epidemics could be controlled, while in Edinburgh favus had been reduced to sporadic occurrence. With rodent ulcer, radium was better than x rays, and the aim was to give the maximum dose in the shortest time that the skin could stand. In lupus the administration of x rays must be done with care so as to avoid overstimulation of the tissues and the production of a lupous carcinoma. Professor GULLAND said that in myelogenous leukaemia his later results with radium were better than with x rays. There was danger that excessive dosage might produce pernicious anaemia, and he advised that the reduction of leucocytes should not be carried below 20,000 per cubic millimetre, as reduction continued for some weeks after the last treatment. The same caution was necessary in exophthalmic goitre, where also radium was superior to x rays. In Banti's disease, though great reduction in the spleen took place, there was no absolute cure by radium, and splenectomy was necessary.

Professor Sir HAROLD STILES said that he preferred radium to operation in lymphadenoma. In cancer of the rectum and colon he advised that if there was any doubt as to complete removal, radium should be left at the site of operation. There was need of experimental investigation of radium, and of more precise knowledge of its action upon living tissue and of its dosage. Dr. HOPE FOWLER pointed out that radium treatment was particularly suited for those damaged by x rays. There was need of careful regular blood examination in irradiated patients. Lymphatic tissues were more amenable to radiation than epithelial.

Dr. NORMAN WALKER thought that Dr. Knox had been too pessimistic about the x-ray treatment of ringworm. There was no doubt that lupous carcinoma had greatly increased since the use of x rays, and that this treatment carried a serious risk of this complication. Mycosis fungoides showed great benefit under x-ray treatment. Indiscriminate x-ray treatment for superfluous hair in women often produced bad end-results in atrophy of the skin and lymphangiectasis. Dr. LOGAN TURNER said there was need of apparatus that would allow of the application of radiation to growths in concealed cavities such as the larynx. Mr. D. GREIG spoke of the failures of this treatment, and cited cases of mycosis fungoides as instances. He deprecated undue optimism.

PROFESSOR RÖNTGEN has been elected a doctor honoris causa by the Frankfurt Faculty of Natural Science.

PROFESSOR HUTINEL, who recently resigned his professorship of children's diseases in the University of Paris, has been succeeded by Dr. P. NOLÉCOURT.

Reviews.

INSTINCT AND THE UNCONSCIOUS.

IN *Instinct and the Unconscious*, by Dr. W. H. R. RIVERS, the psychologist and psycho-pathologist will find a work which well repays the most careful study. It opens up new lines of thought, and may be said to meet a definite need. During the last few years remarkable advances have been made in psychology, and the progress which has taken place is in a large measure due to the contributions made by the psycho-pathologist in daily contact with the practical problems of the clinic. The time would now seem to have come, however, when the dogmas, theories, concepts, and terminology of clinical psychology should be subjected to the closest scrutiny. The whole subject needs to be hardened and clarified; it needs constructive criticism, wider view-points, and minute and careful observations. Especially must the endeavour be made to interpret abnormal reactions in terms applicable to the organism as a whole. The facts of clinical psychology need to be harmonized with the whole body of biological and physiological knowledge and to be expressed in the special language of science, because it is only in this way that psycho-pathology can be extricated from the narrow circle of repetitions into which it would seem to be in danger of falling. Such an aim is most likely to be achieved, not by the clinician, who is naturally largely preoccupied by therapeutic considerations, but by the trained psychologist and scientific observer who is in a position to interpret facts with more detachment and with a wider range of knowledge. It is from this wider outlook that Dr. Rivers approaches the problems of mental functioning, and his book may be regarded as a contribution of definite value, and as a real addition to our knowledge of the subject with which it deals.

The expressed aim of the book is to develop a biological view of the psycho-neuroses, and the endeavour is made to bring functional disturbances of the mind and nervous system into relation with the concepts concerning their normal modes of working which are held by the biologist and physiologist. Dr. Rivers sets himself more particularly to consider the general biological function of the process by which experience passes into the region of the unconscious. This process he calls *suppression*, and he takes the view that this process occurs—especially as the result of physical and mental shock—without the intervention of volition, and that it is to be regarded as an active and especially complete form of forgetting. He limits the content of the unconscious to experiences of this kind which are not capable of being brought into the field of consciousness by the ordinary processes of memory or association. The relation between suppression of psychological experiences and certain physiological phenomena is next considered, and it is shown by reference to the work of Head, Rivers and Sherren in respect to protopathic and epicritic sensibility that in the former mode of cutaneous sensibility we find evidence of suppression at the physiological level analogous to that which occurs at the psychological level. The argument is thus developed that suppression of conscious experience is only one example of a process which applies throughout the whole of the animal kingdom, and is essential to the proper regulation of every form of human and animal activity. Every living process of the animal involves, not only activity directed to a special end, but also the inhibition of tendencies to activities of other kinds. Thus suppression is to be regarded as only one aspect of the universal physiological property of inhibition.

In chapters on "The content of the unconscious," "The nature of instinct," "The danger instincts," "Suppression and the all-or-none principle," and "Instinct and suppression," Dr. Rivers develops smoothly and consistently his central contention that the same biological principles are operative at the psychological levels of development as at the sensori-motor and reflex levels of activity. The treatment of these subjects is most suggestive and full of interest. As an example may be cited a subject upon which Dr.

Rivers lays particular emphasis, namely, the protective reaction to danger by means of immobility. In suggesting that hysterical symptoms—paralyses, mutism, anaesthesia—are modified forms of this instinct he has undoubtedly brought into prominence a point of view of considerable significance, and one which might be utilized for the elucidation of other forms of abnormal reactions. His views would seem to be particularly applicable to the negativistic behaviour which is such a prominent feature in cases of dementia praecox. The thought suggests itself that we here find a much purer form of the instinct of immobility than that found in the hysteric. This is to be expected, as the reactions in dementia praecox are extremely primitive in character and expressive of a much deeper stage of regression than are those of hysteria. In the "death feint" the threatened animal can be pushed about and rolled over without any apparent response—a state of affairs which is almost paralleled in the postures, tensions, and attitudes of many katonic cases. The negativism in dementia praecox may thus be regarded as a biological protective reaction which guards the patient, not from physical danger, as in the case of the immobile animal, but from undesired intrusions into his inner mental life.

In subsequent chapters Dr. Rivers deals with "dis-sociation," "the complex," "suggestion," "hypnotism," "sleep," "hysteria," "sublimation," and "regression." It is, of course, outside the scope of a review to discuss his treatment of these subjects, but some brief reference may perhaps be made to the views which Dr. Rivers has formulated in regard to Freud's psychology. His attitude is developed more fully in the appendix to this volume, which contains two articles entitled respectively "Freud's psychology of the unconscious" and "Freud's conception of the censorship." There is no doubt a very large measure of truth in Dr. Rivers's view that Freud's theories have been pushed by their advocates beyond the position they are entitled to hold, with the result that, failing to fulfil the expectations thus aroused, their merits may be underestimated, or even be in danger of being thrust into the limbo reserved for dead hypotheses, only to be rescued therefrom by some later generation. He is probably correct, moreover, in suggesting that the excessive absorption in the sexual determinants of human reactions which characterizes the followers of Freud is to a large extent a reaction from the timidity and prudery of the past in relation to sexual matters, and is a protest against the ignorance of this side of life which often exists. One outstanding merit of Freud's psychology, as Dr. Rivers recognizes, is the emphasis he has laid on the fact that human reactions, both normal and morbid, are determined by the totality of the individual experience as well as that of the ancestral or racial experience; not only has he recognized this fact, but he has devised methods which, when judiciously used, are of considerable practical utility, for by means of them the historical past of the individual may be brought to light.

As indicated above, Dr. Rivers devotes considerable attention to the vexed question of the censor—a concept which bulks so largely in Freud's psychology. This concept of an anthropomorphic entity, itself unconscious, standing between the true unconscious and preconscious, is artificial and obviously needs further examination. Dr. Rivers contends that a concept which is based on analogy with a highly complex and specialized institution should be capable of being expressed in some other and more satisfying form. He maintains that it is to physiology rather than sociology that we should look for the clue to the nature of the process by which a person is guarded from the intrusion of disturbing elements of his unconscious experience, and he proceeds to develop a view which harmonizes with the biological principles maintained throughout the book. Assuming the organization in the unconscious of a functional hierarchy such as exists in the nervous system, he goes on to show in regard to dreams that the relaxation of conscious control in sleep must result in the emergence of mental activities identical in form and structure with the thoughts, feelings, and conduct peculiar to the infantile stage of mental development. This is not the place to either epitomize or discuss the views which Dr. Rivers brings forward. It may be said, however, that they are highly suggestive and appear to afford a better explanation of the effortless mental activity

which may be assumed to accompany the repose of the psycho-physical organism during sleep, than does the concept of the censorship with its suggestion of strain, vigilance, and tension.

In addition to the papers above mentioned, the appendix contains reprints of several articles by Dr. Rivers relevant to the subjects dealt with in the first part of the book. We notice a rather unusual number of mistakes in printing, and the first sentence on page 232 is in a particularly unhappy condition.

Dr. Rivers has written a most interesting book, and one which we can unreservedly recommend to our readers.

THE MEDICAL TREATMENT OF EXOPHTHALMIC GOITRE.

In *Exophthalmic Goitre and Its Non-Surgical Treatment* Dr. ISRAEL BRAM,² who is instructor in clinical medicine under Professor Solomon Solis-Cohen at the Jefferson Medical College, Philadelphia, insists with no uncertain voice that operative treatment of the thyroid is futile in primary hyperplastic goitre of Graves's disease, and that nearly every such case, if not moribund, is curable by non-surgical means of one kind or another. While condemning operations on the thyroid in primary exophthalmic goitre Dr. Bram frankly admits that removal of nasal polypi, adenoids and diseased tonsils, a chronically inflamed "controlling" appendix, or an affected portion of the female pelvic organs, may cure hyperthyroidism; and further he approves operation on a simple non-toxic goitre of some standing on which symptoms of Graves's disease have recently been superimposed. After a full account of the various opinions held as to the pathogenesis, and after numerous quotations from McCarrison, Crile, and others, the conclusion is reached that both simple and toxic goitres depend upon factors outside the thyroid. The analogy of appendectomy which has been urged in favour of thyroidectomy in Graves's disease does not hold good; for appendicitis is a local disease which reflexly produces symptoms, whereas exophthalmic goitre is secondary in etiology.

As the possible causes and manifestations of the disease are numerous, it is not surprising that many remedies sometimes act beneficially; thus most patients are made worse by iodine, but occasionally its administration has brilliant results; some patients improve on an ample beef diet, whereas others react favourably to vegetarianism. The important section on prophylaxis gives the details of Marine and Kimball's extensive and successful experience in the prevention of goitre by sodium iodide given to 1,000 schoolgirls in the Great Lakes goitrous area. In the account of the hygienic treatment of the disease the importance of removing any possible causal factor is emphasized, and then, in connexion with the subject of rest, it is pointed out that in the average case "a rest cure rests neither body or mind," and that accordingly complete rest in bed is contraindicated, except in dangerous cardiac insufficiency. The dietetic treatment is carefully discussed, the objections to a meat regimen are mentioned, and a number of diet sheets are given. Medicinally quinine, especially the hypobromate (gr. v, t.d.s.), is the drug of choice. In the shrewd and practical remarks on psycho-therapy attention is drawn to the value of making the patient laugh, and to the therapeutic use of music, according to the patient's taste; thus, "even jazz, the prototype of cubism in art," may be beneficial. Although the psycho-therapeutic measures necessary may impose a difficult task on the medical attendant, the results fully compensate for the pains expended. Written in a rather breezy style, this monograph may perhaps arouse criticism, but it shows practical wisdom combined with a good acquaintance with the literature of a subject much to the fore in the United States.

AMERICAN MEDICAL BIOGRAPHIES.

American Medical Biographies, by Professor HOWARD A. KELLY and Dr. W. L. BURRAGE,³ is the expansion of the

biographical part of Professor Howard Kelly's *Cyclopaedia of American Medical Biography*, which was published in 1912, and contained introductory chapters on the history of several of the specialties, a number of portraits, and 1,184 biographies. The present volume contains 1,948 biographies, and thus provides succinct information about the medical worthies of the United States of America and Canada for more than 300 years, ending with the year 1918. The principle of selection has been to include every man or woman who has in any way contributed to the advance of medicine in the United States or Canada, or who, being medically qualified, has become distinguished in general science or in literature. The list contains stars of the first, second and third magnitude, and naturally the question of admission often arose; in coming to a decision the editors "cultivated a catholicity of judgement that broadened as the work progressed." In addition to a general alphabetical index, there is a local index in which an attempt has been made to give the chief places of practice of the worthies in this book alphabetically by states, territories, and the provinces of Canada. The first name in the first state, Alabama, in the local list is that of J. Y. Bassett, made so familiar as "An Alabama Student," by the late Sir William Osler, who contributed this and other biographies to this work. The State of Utah and Prince Edward's Island each have two names to their credit, New York nearly 500, Pennsylvania over 300, and Massachusetts about 250. The bibliographies resemble those in the *Dictionary of National Biography*, and, though not all signed, are by various hands; one of the longest, that on Benjamin Rush, "the American Sydenham," occupying about seven columns, is by Dr. F. R. Packard, and one of the most charming is Professor Howard Kelly's account of Colonel John McCrae, the author of "In Flanders Fields." Most appropriately the work is "dedicated in love and esteem to the memory of Sir William Osler," whose lifelong interest in the subject did so much for medical biography and its study in America. The labours of Professor Howard Kelly and Dr. Burrage have been crowned by success, for they have provided a source of reference from which many will draw for many years, and on all accounts they deserve our sincere thanks and congratulations.

NOTES ON BOOKS.

THE second edition of *Diseases of the Chest*,⁴ by Professors LANDIS, NORRIS and KRUMBHAR, of the University of Pennsylvania, provides the student and medical practitioner with an excellent work on the principles and practice of the physical diagnosis of diseases of the chest. The first edition of this book was reviewed less than four years ago (*BRITISH MEDICAL JOURNAL*, 1917, ii, 796), and it suffices to say that the present edition has been well brought up to date and amplified where necessary. The volume contains a great deal of valuable information as to the how and the why of the physical signs upon which diagnosis so largely rests, and should be within reach of all medical students.

Volume XIV of a *Traité de Pathologie Médicale et de Thérapeutique appliquée*,⁵ published under the direction of EMILE SERGENT, L. RIBADEAU-DUMAS, and L. BABONNEIX, deals with parasitic infections. Several authors—Neveu-Lemaire, Ameuille, Troisier, Paiseau, Gouzien, Abrami, and Raymond—contribute to it. The part will appeal to tropical workers, as helminthiasis, protozoology, and other tropical diseases appear in its pages. Neveu-Lemaire deals with coccidiosis, and the new work by Dobell on this subject is incorporated. The helminthic chapters give a very good account of the subject, on the whole, though perhaps there is nothing very new to report. Trypanosomiasis, malaria, leishmaniasis, dysentery, spirochaetosis, rat-bite disease, are some of the other subjects dealt with. The volume with index runs to 577 pages. The illustrations are somewhat scanty, but those that do appear are quite good and instructive. The coloured plate on malaria

⁴ *Diseases of the Chest and the Principles of Physical Diagnosis*. By George William Norris, A.B., M.D., and Henry R. M. Landis, A.B., M.D. With a chapter on the Electrocardiograph in Heart Disease, by Edward B. Krumbhaar, Ph.D., M.D. Second edition, revised. Philadelphia and London: W. B. Saunders Co. 1920. (Roys. 8vo, pp. 844; 433 figures, 35s. net.)

⁵ *Traité de Pathologie Médicale et de Thérapeutique appliquée*. Publié sous la direction de Emile Sergent, L. Ribadeau-Dumas et L. Babonneix. XIV: Infections Parasitaires. Par Neveu-Lemaire, Ameuille, J. Troisier, Paiseau, Gouzien, Abrami, et Raymond. Paris: A. Maloine et Fils. 1921. (Demy 8vo, pp. 577; 145 figures, 2 1/2 francs. Fr. 30; post free, Fr. 33.)

² *Exophthalmic Goitre and Its Non-Surgical Treatment*. By Israel Bram, M.D. London: Henry Kimpton. 1921. (Med. 8vo, pp. 438, 30s. net.)

³ *American Medical Biographies*. By Howard A. Kelly, M.D., LL.D., F.A.C.S., Hon. F.R.C.S. (Edin.), and Walter L. Burrage, A.M., M.D. Baltimore: The Norman Remington Company. 1920. (Double crown 8vo, pp. 1339.)

is not very good; it might have been better for a book of this kind. The descriptions of the diseases are full and up to date, and the book may be recommended to those who read French.

A COMPENDIOUS but expensive students' handbook of treatment is provided by Professor FINKELBERG of Bonn, aided by a dozen contributors, in the form of Therapy at Bonn University Clinic.⁶ The first five hundred pages deal with medicine and surgery; the remainder is devoted to gynaecology, cutaneous diseases, and special forms of treatment. It is doubtful whether the whole subject of treatment is capable of compression within the narrow limits of a book of this size, if practical utility is to be considered and if generalities, useless to the beginner, are not to take the place of the detailed advice for which he is always seeking.

⁶ *Die Therapie an den Bonner Universitätskliniken*. By Professor Dr. Rudolf Finkelberg, in Bonn. Dritte, vermehrte Auflage. Bonn: A. Marcus and E. Webers. 1920. (Cr. 8vo, pp. 757, 7 figures. M. 36; bound M. 44 40)

APPLIANCES AND PREPARATIONS.

A Double Retinoscope.

DR. R. C. MACDONALD (Inverness) writes: With the double retinoscope here illustrated refraction is more easily and more accurately performed, the shadows are more vivid, and the illumination better than with any single instrument, and the operator has the benefit of vision with both eyes, and if he is ametropic can wear his correction. Correction can be made

to an eighth of a dioptré or less, and good results can be obtained even in daylight. An ordinary bulky electric, argand, or other lamp is used over the patient's head in the usual way. The instrument must first be adjusted to the interpapillary distance of the operator; then the reflection is thrown on a screen at the working distance preferred—say one metre—and the two reflections are accurately superimposed so as to make one circle of light. On looking through the in-

strument, at the eye a brilliant reflex is seen by both eyes simultaneously. No further adjustments are required unless another operator wishes to use the instrument. An electric model is also made, and the instrument can be obtained with concave or plain mirrors according to choice. The instrument is made for me by Mr. Robert Whitelaw, surgical instrument maker, Woolmanhill, Aberdeen.

Menthofax Ointment.

Methyl salicylate, which is rapidly absorbed when rubbed into the skin, is often employed as a local application in chronic rheumatism and neuralgic affections. Messrs. Burroughs, Wellcome and Co. now prepare a compound methyl salicylate ointment to which they have given the name "menthofax." This contains—in addition to some 50 per cent. methyl salicylate—menthol, eucalyptol, and oil of cayenne. It is packed in collapsible screw-topped tubes for use when an analgesic and rubefacient application is needed.

MESSRS. J. AND A. CHURCHILL announce for early publication *Critical Microscopy*, by Dr. A. C. Coles.

WE have received from the Disabled Society a pamphlet compiled by Captain H. C. Baird, D.S.O., "for the general guidance of ex-service men of all ranks who have lost one or more arms or legs." Its fourteen pages contain a good deal of information which should be useful to persons who have undergone amputation as to rates of pension and other benefits to be obtained by disabled ex-service men. We fear that it may be too late to protest against the absurd but widespread practice of describing a man who has perhaps three and three-quarter limbs instead of four as "limbless."

THE SEARCH FOR A SPECIFIC TREATMENT OF TUBERCULOSIS.

A BACTERIOLOGIST'S ATTEMPT.

ATTENTION has recently been called in the public press to a specific method for the treatment of pulmonary tuberculosis devised by Henry Spahlinger, a Swiss bacteriologist. Professor Letulle communicated to the Académie de Médecine on April 23rd, 1914, a note in which it was stated that the method consisted of a series of intramuscular injections of a combination of tuberculous antigens and of ferments, and that this "specific" treatment was combined with an "auxiliary" treatment composed of ferments associated with lipoids, which were administered either intramuscularly or intravenously. A considerable number of cases were, we believe, treated at the City of London Hospital for Diseases of the Chest and possibly elsewhere in London at that time, and it appears that some of them survive; how many were treated and how many survive we have not been informed. We have received from Dr. A. H. Croucher of Eastbourne a letter, dated February 14th, transmitting a translation of a note which he informs us was deposited by M. d'Arsonval at the Académie des Sciences in Paris on February 7th. In this note it is stated that the material used consists of *antigens and ferments obtained from the tubercle bacilli*. The antigens, it is stated, are separately inoculated in increasing doses, according to a fixed scale, so that at the end of several months an injection of all the components of the bacillary bodies is made. The note goes on to say that treatment by this method has been carried on from 1915 to the present time in Switzerland, France, and England; Dr. Croucher reports that all the cases known to him treated six years ago were still alive and capable of carrying on their daily occupations at the end of 1920. All the patients, he states, were in 1913 suffering from advanced tuberculosis and two had laryngeal complications. The note contains also a statement by Dr. Leonard Williams, who is represented as stating that certain cases of advanced tuberculosis with bacilli in the sputum treated under his observation by this method in 1912-14 had remained well during the last six years, although they had received no specific antituberculous treatment since 1914. Examination in 1920 showed that their condition was good; there was no trace of active tuberculosis, no cough, and no expectoration.

The statement that the Ministry of Health had sent one of its staff to Geneva to investigate the matter is incorrect, and it is, of course, clear that no useful purpose could be served by such a mission until M. Spahlinger and his friends have made a full statement as to the way in which the material is prepared and have allowed competent bacteriologists to observe their methods. As Dr. Addison said very judiciously at Exeter, "it is most important, having in view the fact that widely published statements may raise unfounded hopes in the hearts of consumptives, that it should be stated as clearly as possible that in the case of this supposed remedy much further investigation will be necessary."

The reports which have so far reached us do not make plain the real nature of Spahlinger's remedy. In the following communication, which we have received from Dr. W. Camac Wilkinson, he assumes it to be in the nature of a tuberculin:

I have read the evidence in favour of the method advocated by the Swiss bacteriologist, M. Henri Spahlinger, and have frankly discussed his point of view with him at a private interview. His method is based on the principle of active immunization by means of the products of the specific tubercle bacillus, and his remedy is therefore specific. He even speaks of antigenic treatment, using the very term I suggested years ago instead of the irrelevant term "vaccination" or treatment by "vaccines." Tuberculin is the antigenic substance and is not a vaccine.

In fact and in principle, M. Spahlinger's method is the self-same method which I have been using for thirty years, and have been advocating in season and out of season for twenty years. M. Spahlinger even has the same views upon "mixed infection" which I have unceasingly championed since the year 1896. Moreover, I can produce at least five times as many cases as M. Spahlinger can, which were treated in 1910, 1911, and 1912, and are still alive and at work in 1921. I therefore view

M. Spahlinger's method in no hostile spirit; indeed, I welcome him as an ally. Our methods are similar, and may be the same. Possibly M. Spahlinger has improved the means of securing immunity by using the products of the tubercle bacillus in a somewhat different and better way or in a modified form.

I must approve of the direct method of treatment that exploits the products of the tubercle bacillus as a means of creating immunity against the live bacillus, and I have abundant evidence that, with care, discrimination, experience, and courage, one can slowly build up a fairly efficient mechanism of immunity—even in advanced forms of pulmonary tuberculosis complicated with tuberculous ulceration of the larynx—by means of these very products. The direct examination of the larynx, of the blood by Arneft's method, and of the expectoration, yields convincing evidence of the value of this method of active immunization by means of the specific products of the tubercle bacillus. If one can obtain these results in the late stages, *a fortiori* the treatment of the early stages must be and is tenfold more successful.

It was to prove the value of these specific products, which, variously modified, I had used in Australia for twenty years with great success, that I came to England in 1909, and established my tuberculin dispensary and its branches; and at the present moment there is no better place for testing the relative merits of my methods and M. Spahlinger's. When I came to England, tuberculin as a remedy for tuberculosis had been abandoned (see Osler's *Medicine*). If I have done nothing else I have made medical men think hard and talk loud of the dangers of tuberculin, till year by year the talk about danger has subsided into a timid whisper; the latest book on tuberculin treatment does not even mention danger. The medical profession may now be in a mood to give a fair and open trial to specific treatment. My work has prepared the way, and I rejoice to think that a Swiss bacteriologist gives this stimulus to research, for which I have been pleading for many years. I personally welcome any fair and open trial of any method of specific treatment, which is most surely the method of the future. But it must be a real trial of the relative merits of our systems by competent judges who have made themselves authorities by work and not by official position.

Such a trial must fulfil strict conditions. Assuming that the trial will be in the hands of experts, I have already laid down the essential conditions in my work published in 1912:

1. The remedy should be the only remedy used in treatment.
2. The remedy should be exploited in a consecutive series of cases of all kinds (not merely specially selected cases), and all the cases fully treated should be published.
3. After treatment the cases should be carefully watched and examined for at least three or four years before a final judgement is given upon the value of the remedy.
4. The results should be arranged in three groups, or better, as in my own records, in five groups, according to the character and degree of the changes in the lungs.

These conditions, I admit, disqualify the work of almost all observers, because, except by myself, tuberculin has never been tested under these conditions. My own observations have been carried out as far as possible under these conditions, and therefore should furnish trustworthy evidence of the value of the method. (*Tuberculin in the Diagnosis and Treatment of Tuberculosis*, p. 477.)—I am, etc.,

W. CAMAC WILKINSON, M.D. Lond., F.R.C.P.,
Director, Tuberculin Dispensary.

THE ADVANCE OF MEDICAL EDUCATION IN CHINA.

A MEETING of members of the medical profession to advance the cause of medical education in China was held in the Barnes Hall of the Royal Society of Medicine on February 21st. Sir DONALD MACALISTER presided over a large gathering, and messages of regret at inability to attend were received from the late and present Chinese Ambassadors, the American Ambassador, and others.

Sir DONALD MACALISTER said that for many years he had been associated with Christian propaganda in China, in particular with medical missions. It had long been his conviction that the true method of spreading Christianity in the East was the method of its Founder, who went about not only preaching the good news of the kingdom,

but healing all manner of diseases. But when the seeds of Christianity had been wisely planted in China its further growth would be conditioned by the measure in which it ceased to be regarded as foreign. The ultimate aim of medical missions in China should be, not to place numbers of British or American doctors all over that land, but by education to build up a Chinese medical profession. That was the spirit of the great educational enterprises centred at Moukden and Peking, and very particularly at the Christian University of Shantung.

Mr. HAROLD BALME, F.R.C.S., of the School of Medicine of the Shantung University, said that western medicine was introduced into China by Colledge, a surgeon of the East India Company, in 1827, and a little later by Parker, a medical missionary from America. The first Chinese medical college was established at Tientsin in 1881, thanks to Kenneth Mackenzie of the London Missionary Society, and the help of Li Hung Chang. Six years later a second medical school for Chinese students was founded in Hong Kong. After the Boxer rising a school of medicine was established in Peking, the result of a combined effort of British and American medical men, and, following this, missionary medical colleges sprang up in other parts of the country—too many of them, indeed, in view of the limited staffs and equipments available. Meanwhile, a body of Chinese medical men, who had received their training in England and America formed a National Medical Association, with Dr. Wu Lien-teh, a graduate of Cambridge, as leader. Other organizations, not specifically missionary, in America, Germany, and Japan took a share in the work of medical education, especially the Rockefeller Foundation, which took over the complete financial responsibility of the Peking College, to which a large staff of expert teachers had been appointed, mostly from the United States, but including thirteen Chinese professors. The Council of Medical Education of the China Medical Missionary Association had asked the Rockefeller Foundation to assist in the support of at least one medical school teaching in Chinese, and had also urged that all missions interested in the advance of medical education in East and Central China should concentrate their forces upon the development of such a school. The school chosen was the one at Tsinan, now the school of medicine of the University of Shantung. The Rockefeller Foundation had asked the school to take over the three junior classes formerly under instruction at the medical college in Peking, and had made a very generous grant towards staffing, building, and equipment. The school had secured a faculty of over twenty full-time teachers, representing some of the leading British and American universities. Similar efforts were being made in Moukden, Chengtu, Shanghai, and other places. The Council of Medical Education had also outlined a two-year course of pre-medical instruction to be taken by students previous to entering upon their five-year medical course. The speaker touched also upon the great improvements in the Chinese nursing service, the interest of the modern Chinese in preventive medicine, and the sympathetic attitude of the Chinese Government. The policy of the Board of Education of China, as stated by a representative of the Board at the last conference of the China Medical Missionary Association, included the provision of a modern medical college in each province, the opening of an institute for research, and the registration of general practitioners.

Sir A. PEARCE GOULD moved:

That having heard with pleasure of the sympathetic interest of the Chinese Government in the development of modern medicine in China, and of the steps which have already been taken by British and American medical practitioners to co-operate with the Chinese in the establishment of medical schools in which the highest standards are set, this meeting of members of the British medical profession desires to place on record an expression of its sympathy with this effort, and its willingness to promote in every way possible the advance of medical education in China.

He remarked on the ancient civilization of China, that at a period when we in Europe were without measure of time or a craft to our fingers, the Chinese were expert astronomers and proficient in the fine arts. It was unthinkable that a people who had been so great in the past and still had such wonderful powers of grasping modern science—as was proved by the work on plague prevention

carried out by Chinese graduates—should not carry the lamp far ahead once it was placed in their hands.

Mr. McADAM ECCLES, in seconding the resolution, said that he believed that medical education in China would result in diminishing, if not abolishing, what was called the "Yellow peril."

The resolution was carried unanimously.

Dr. H. G. EARLE, Dean of the Medical Faculty of Hong Kong University, expressed his appreciation of the work of the China Medical Missionary Association. Last year he attended its biennial conference, which was split up into scientific sections, where a great deal of original research was brought forward. In Hong Kong all the special buildings for medical work—physiology, anatomy, tropical medicine—were the result of donations from the Chinese community. He always told his students who wanted to visit England or America to qualify in their own country first, and the provision of post-graduate facilities here for Chinese graduates would to no small extent advance medical education in China.

Dr. L. SAMBON suggested that not only should the results of Western research be carried to China, but that we in the West should study the ancient medical knowledge of China and of the Orient generally. China first taught the treatment of syphilis by mercurial preparations, and we owed the prevention of small-pox in some degree to China, though more to India.

Mrs. SCHARLIE proposed a vote of thanks to the Chairman; and Sir JOHN JORDAN, late Minister Plenipotentiary to Peking, in seconding, said that although the British were the pioneers of medical work in China, and for a long period carried it on alone, they had now yielded to the Americans in this respect, greatly to the loss of British influence and prestige. The best intellect of China was now being trained in the United States, where in a single city there were gathered more Chinese students than in the whole of this country.

LUNCHEON TO THE EDITOR OF THE "BRITISH MEDICAL JOURNAL."

SIR DAWSON WILLIAMS, Editor of the BRITISH MEDICAL JOURNAL, was entertained by the Council of the British Medical Association at a complimentary luncheon at the Hotel Cecil on Wednesday, February 16th, in recognition of the knighthood conferred upon him at the New Year by the King. Dr. R. A. BOLAM, O.B.E., Chairman of Council, presided. The toast of the King having been duly honoured, the Chairman referred to Sir Dawson Williams's long connexion with the BRITISH MEDICAL JOURNAL, and to his appointment as Editor in 1893. He was sure that they were all deeply glad that Sir Dawson Williams's work for the Association, for the profession of medicine, and for the community at large, had been recognized in the way it had been by His Majesty the King. Sir Dawson Williams had always been willing to give every assistance and advice in his power, and though some of them had not always found his opinion the same as their own, they knew that the view expressed was given honestly and without fear.

SIR CLIFFORD ALBUTT, President of the Association, referred to his long friendship with Sir Dawson Williams and to the many accomplishments of their guest. He said that if one tried to put into a word, or into a few words, the character Sir Dawson Williams set before them, he thought they would feel that that combination of breadth of view and sympathy, and a fine kind of understanding and knowledge of the world, was summed up in the single word, wisdom—he was a particularly wise man. Another quality was his impenetrable modesty. His presence at the head of what was the greatest medical journal in the British Islands had been of very great benefit to the affairs of the British Medical Association, and had helped to bring it to the high position it now held. The Editor was from time to time called upon to deal at once with matters affecting the profession which were suddenly raised and were afterwards the subject of full consideration and discussion. He had always been astonished at the skill with which the Editor had dealt with such matters when first arising.

Dr. J. A. MACDONALD said he wished to add his quota to the appreciation of Sir Dawson Williams, because probably he had had more intimate intercourse with him than anyone else in the assembly during the twenty years for which he had been closely connected with the work of the Association; he would like to add something to what Sir Clifford Albutt had said of their guest's public career by which he had made his name. From all he had heard, particularly from those who attended the special meeting of the Association in London in 1919, the appreciation of Sir Dawson Williams was world-wide. Every man with whom he had spoken in that great assembly of the medical profession referred to Sir Dawson Williams's wonderful presence, and his way of getting at the heart of things and giving a good sound opinion. With regard to the JOURNAL, it had taken the head place of medical journalism in the world. He had consulted Sir Dawson Williams on many occasions, and his opinion, once obtained, was invaluable. There was no man in the whole of the medical profession whose opinion and knowledge of affairs was so much appreciated as that of their guest, but it was often difficult to get.

The CHAIRMAN then formally proposed the health of Sir Dawson Williams, which was received with musical honours.

SIR DAWSON WILLIAMS, who on rising was received with acclamation, thanked those present for the reception accorded him. The fact that the honour of knighthood had been conferred upon the Editor of the *Lancet* showed that the desire was that the work done by the medical journals in connexion with the war should be officially recognized. That being so, he was of course pleased that the JOURNAL of the Association was included in the recognition. The war brought about a position of gradually increasing difficulty for medical journalism. It entailed, among other things, a change in the scope of the JOURNAL, as probably two-thirds of the active medical profession were engaged in military surgery and medicine. If he was right in believing that the honour conferred upon him was due to action taken by influential members of the general press, it was interesting to remember that the general press was founded some three hundred years ago by a doctor of medicine. During his long connexion with the JOURNAL, and especially during the twenty-three years he had been Editor, he had seen great and beneficial changes in its character; he hoped the progress might continue. The JOURNAL had two main functions to discharge. First, the dissemination to members of the Association of information on the progress of clinical medicine and the sciences on which it rested; and that, in his view, was by far the most important duty, for the very practical reason that as the profession became more efficient in the prevention and cure of disease, so its influence in Parliament and in the general community would increase, and further, in this way only would quackery be extinguished. The other important work was to disseminate information as to what was being done by the Association in connexion with medico-political affairs. He had always received the greatest kindness and consideration from all the officers of the Association, and especially from Dr. Macdonald during all the trying time he was Chairman of Council until his recent retirement.

The following letter was addressed to the Editor of the JOURNAL on January 3rd by the senior member of the printing staff of the BRITISH MEDICAL JOURNAL:

Dear Sir,

At a specially convened meeting, held on January 1st, the Printing Staff of the BRITISH MEDICAL JOURNAL resolved unanimously to tender you their sincere congratulations on receipt by you of the honour of Knighthood at the hands of His Majesty the King.

The Printing Staff feel that your arduous labours on behalf of the Medical Profession, on the one hand, and of suffering humanity on the other, richly deserve this well-merited recognition by the head of the State; they also trust you may be spared for many years to continue your good work and enjoy the honour conferred upon you.

On behalf of the Printing Staff, I beg to remain,

Your most obedient servant,

J. R. PEARCE,
Father of the Chapel.

Sir Dawson Williams,
Editor, BRITISH MEDICAL JOURNAL.

British Medical Journal.

SATURDAY, FEBRUARY 26TH, 1921.

HOSPITAL STAFFS.

THE discussion on the future provision of hospitals, and particularly as to the maintenance of the voluntary system, has during the last few months passed into a more satisfactory phase. Hasty generalizations and panic-stricken suggestions, turning everything topsy-turvy, have given place to a spirit of reasoned inquiry and careful investigation of facts. The proposal contained in the hospital clause of the Ministry of Health (Miscellaneous Provisions) Bill would have given the council of a county or county borough power to establish and maintain a general hospital; the council would have had power to borrow money, if necessary, in order to establish the hospital, and would have maintained it out of the rates. Very little consideration of the inevitable effect of these proposals in checking the flow of public benevolence was sufficient to convince all persons acquainted with the way in which voluntary hospitals are maintained that the clause would, if carried into law, before long bring the voluntary system to an end. Dr. Addison consented to withdraw the proposal and undertook to appoint a committee to inquire into the financial position of voluntary hospitals. The clause as it reached the House of Lords still provided that a county council should have power to take over a Poor Law hospital or infirmary and maintain it as a hospital for the treatment of illnesses or diseases generally or for any particular illness or class of illness. The rejection of the whole bill on the second reading in the House of Lords has not interfered with the activities of the committee which is now sitting under the chairmanship of Viscount Cave, and evidence has been given before it on behalf of the British Medical Association.

It is of course obvious that the medical profession is greatly interested in many parts of the subject Lord Cave's committee is considering. The British Medical Association was in fact the first to draw attention to an aspect of the matter which has since attracted a great deal of notice. The conference of staffs of voluntary hospitals, held at Cambridge during the annual meeting last year, to consider the question of the treatment of State-supported patients, had for one result that it brought into prominence the fact that the number of such patients is very considerable. Another conference on the same subject was held in London on December 21st, when resolutions were passed reaffirming the belief that the existing method of maintenance and staffing of the voluntary hospitals is to the advantage of the public and medical science, and of the medical profession. The subject has been fully discussed also at conferences of the profession in Scotland, held in Edinburgh at the end of July and early this month. As will be seen from the report published in the SUPPLEMENT this week, the conference in Scotland arrived at the conclusion that the present methods of administration of the voluntary hospitals should be continued, and the opinion was further expressed that it was not desirable that voluntary hospitals should be subsidized by the local rating authorities, except in so far as payment is made for the examination and the

care of patients for whom these authorities are responsible. There is thus general agreement that the status of patients for whom the State is responsible differs from that of other hospital patients, and that not only should the hospitals be reimbursed for the cost of maintenance, but the medical staffs should receive remuneration for their treatment.

The recent report of King Edward's Hospital Fund for London, to which reference was made in our issue of February 5th, has stated the position with regard to hospitals in London very clearly, and the same principles apply to many other voluntary hospitals, including practically all those in other large cities. The Council of the Fund pointed out that as the demand for hospital treatment grows the voluntary system must either expand so as to meet the whole of the growing demand, or confine itself to meeting the whole of the need in the particular kind of demand which it may be best fitted to meet, refraining in the latter case from opposing the establishment of other agencies to meet other parts of the need. It is suggested that different plans may be appropriate to different localities or to different kinds of hospital, and at the first conference of the British Medical Association—that at Cambridge—it was pointed out that the teaching hospitals formed a very special case. The staffs of such hospitals will, as a rule, prefer to be paid for their work as teachers rather than for the time and skill they give in the treatment of patients.

There seems to be a good deal in the argument of the King Edward Hospital Fund that, as the present sphere of the voluntary hospital is the result of a process of specialization, so possibly the best use of the voluntary hospital accommodation and equipment, present and future, would be promoted by some further development of this principle of partial specialization, the specialization taking place probably best between a parent hospital and branches, such as homes of recovery, convalescent homes, or, as has happened at St. Mary's Hospital, London, between the voluntary hospital and the non-voluntary hospital, established possibly in a Poor Law infirmary, and maintained by a local authority under some such provision as that in the Miscellaneous Provisions Bill of the Ministry of Health.

THE FOOD FACTOR IN PELLAGRA.

ALTHOUGH the etiology of pellagra is still in doubt the belief that it is due to a defect in diet has gained ground. Castellani and Chalmers, in the last edition of their *Manual of Tropical Medicine*, observe that modern work tends to support the theory that the absence of a vitamin is the true cause of the disease, but they recognize that there are difficulties in the acceptance of this view. A diet largely of maize, especially if damaged, has been believed to be the cause: maize in itself cannot be the cause, as the disease occurs in countries—as, for instance, England and Scotland—in which maize is not a staple article of diet. Possibly an explanation of the belief is to be found in the fact that in regions where maize is a staple food the diet has a low protein value; the absence or the presence in insufficient quantities of a vitamin may also play some part in causation. Any careful contribution to the subject is therefore to be welcomed, and we propose to give a short account of the results of an interesting experiment recorded in the *Bulletin* (No. 120) of the Hygienic Laboratory of the United States Public Health Service, for the facts have some bearing on general principles.

The experiment, which resulted in the production of pellagra, is described by Joseph Goldberger and G. A. Wheeler. The subjects were adult male convicts who volunteered. Of the 12 who entered the experiment, 11 remained throughout; one had to be released on account of a physical infirmity. The controls to the experiment consisted of 108 convicts, of whom 35 were under observation for a period comparable to the period of observation of the subjects of the experiment. Minute precautions were taken to ensure the segregation of the volunteers and to exclude all factors, such as risk of infection, which might have complicated the results. The volunteers were required to do light work. The experiment fell into two periods—one extending from February 4th to April 19th, during which the volunteers were kept under observation without any change in the regular prison fare. Pre-existing pellagra was thus excluded. The second period extended from April 19th to October 31st; during it the volunteers subsisted on the experimental diet. The diet of the convict controls provided an average of approximately 3,500 to 4,500 calories, yielded by about 90 to 110 grams of protein, 95 to 135 grams of fat, and 540 to 580 grams of carbohydrate. Approximately, 20 to 35 per cent. of the proteins was from animal food. This diet was superior to the experimental diet with respect to the proteins, mineral constituents, and antineuritic and fat-soluble vitamins. The ingredients of the experimental diet were highly milled wheat flour, maize meal and grits, corn-starch, white rice, cane sugar, cane syrup, sweet potatoes, pork fat, cabbage, "collards," turnips, turnip greens, coffee, baking powder, salt, and pepper. During the first three months some buttermilk was used in making wheat biscuits. The average intake of the volunteers varied approximately between 2,500 and 3,500 calories. The average intake of protein varied between 41 and 54 grams, of fat between 91 and 134 grams, and of carbohydrate between 387 and 513 grams; 80 to 90 per cent. of the total protein was from cereal sources (wheat, maize, rice). The antineuritic vitamin content was planned to be low, but in the absence of any distinctive clinical manifestations of beri-beri the observers consider that the amount of this vitamin was not appreciably deficient for the needs of the volunteers during the period of study. Similarly, in the absence of recognizable indications of scurvy the diet was considered to have included an adequate supply of antiscorbutic factor. With regard to the adequacy of supply of vitamin A the observers found it difficult to judge by reason of the meagreness of the available fundamental data; none of the volunteers, however, developed xerophthalmia. The intake of mineral ingredients of the diet was decidedly low.

On this dietary six out of eleven convicts who were submitted to the test for its full period developed pellagra; the characteristic rash occurred with particular frequency on the scrotum. The observers conclude that "in relation to the production of pellagra the study suggests that the dietary factors to be considered as possibly essential are (1) an amino-acid deficiency; (2) a deficiency or faulty constitution of the mineral supply; possibly, but doubtfully, (3) a deficiency in the fat-soluble vitamin intake; and, perhaps, (4) an as yet unknown (vitamin?) factor. As to which or what combination (or combinations) of these constitutes the specific pellagra-producing dietary defect or defects remains to be determined. The experimenters attach little importance to the low content of the food in "anti-neuritic" vitamin.

In another paper M. X. Sullivan deals with the effects of this pellagra-producing dietary on fowls,

pigeons, and rats. He found that fowls speedily began to suffer from polyneuritis, pigeons had convulsive seizures and a few typical polyneuritis; rats speedily lost weight, and exhibited marked evidence of malnutrition, several dragging their hind limbs a short time before death.

The Goldberger diet was thus markedly deficient in antineuritic vitamin for animals, and therefore deficient in this vitamin for man. On the evidence afforded by these papers, it would seem that Goldberger and Wheeler have attached too little importance to the effects of an insufficient supply of vitamins in the production of pellagra. The work of British observers in this field of research would appear to link up with that of their American colleagues. McCarrison, in papers published in this journal, has drawn attention to the profound changes in the digestive organs which result from deficiency of vitamins, changes which would appear to simulate closely those found in pellagra. He has insisted that the term "antineuritic" as applied to vitamin B is misleading, since it directs attention to changes in one system of the body only, while others of equal importance take place earlier, such as those in the organs of digestion and assimilation which lead to the early appearances of digestive disturbances. He has shown also that deficiency of vitamins causes profound changes in the endocrine regulators of metabolism, and especially in the suprarenal glands. May it not be that the inadequate supply of protein to the body tissues, shown by the work of the Committee of Inquiry into Pellagra among Turkish prisoners of war to be so important in the genesis of pellagra, is due primarily to a failure in the organs of digestion and assimilation and of the endocrine organs, consequent on vitamin deficiency? Goldberger and Wheeler appear to have excluded the antiscorbutic factor as devoid of importance in their dietary; but here again McCarrison's work has emphasized that profound changes take place in the suprarenals before clinical evidences of scurvy are present.

The American observers are to be congratulated on their admirable contribution to our knowledge of pellagra. It seems probable, however, that while the suitability of protein is of the highest importance, it is not likely to be adequately utilized by the body tissues in the absence of a sufficiency of vitamins.

THE CZECHO-SLOVAK PUBLIC HEALTH DELEGATES.

The delegation from the Ministry of Public Health and Physical Education of Czecho-Slovakia, to which reference was made last week, spent altogether rather more than a fortnight in England. They were the guests of the International Health Bureau (Rockefeller Foundation), and their visit to this country was preceded by a two months' tour of the United States; they have now gone to Paris. In London they have had the advantage of hearing a detailed exposition of health administration in England and Wales from Sir George Newman and other medical officers of the Ministry of Health, followed by a series of lectures and demonstrations on special subjects. Among these has been a lecture on special schools for deaf and dumb and crippled children, by Dr. Eichholz, of the Board of Education; on maternity and child welfare, by Dr. Janet Campbell; on port sanitation, by Dr. R. J. Reece; on food inspection, by Dr. A. W. J. MacFadden; and on the voluntary general hospitals, by Sir Napier Burnett. The clinical unit system at University College Hospital has been explained to them by Professor T. R. Elliott, the

venereal disease clinic at St. Thomas's by Lieut.-Colonel Harrison, the most recent appliances for field sanitation by Colonel P. S. Lelean, at the Royal Army Medical College, and the training of sanitary inspectors, by Mr. E. W. Wallis, at the Royal Sanitary Institute. A visit has also been paid to the Medical Research Council's laboratories, the Government lymph establishment, and a model farm for milk production. Opportunities have been given for the inspection of the arrangements of the Metropolitan Water Board for pumping, storage, and filtration, the London fever hospital and ambulance service, and the control of the city markets. A day has been found for the enjoyment of municipal hospitality at Brighton, where the delegates inspected a sanatorium and an open-air school of a new type, and on another day they were the guests of Cambridge University. In summarizing their impressions just before departure, the delegates said that of all the institutions which they had learnt even in a short while to admire in England, the voluntary hospitals were pre-eminent; in their own country the hospitals are county or State institutions. Next to these the English system of school hygiene most impressed them, and they hope forthwith to establish a similar system of medical inspection and treatment in the schools of Czecho-Slovakia. From the general efficiency of our municipal health service, particularly in connexion with tuberculosis and venereal diseases, they gathered the lesson that it was very important that the areas of administration should be sufficiently large, and they proposed that such work in these directions as is done in Czecho-Slovakia shall be transferred from the authorities of small districts to the authorities of counties. The education of sanitary inspectors and health visitors has interested them, and though it would not be possible for them to copy the English system in its entirety, they hope to make use of some of its suggestions. At Dr. Addison's invitation the delegates had an opportunity of studying housing schemes in two localities, and expressed admiration for the way in which the Ministry of Health had tackled a problem of which they had had some experience in Prague. In expressing their thanks for the kindness and hospitality they had everywhere received, they expressed special appreciation of the assistance of Dr. J. A. Glover, of the Ministry of Health, who had accompanied them throughout their English tour. The Ministry of Public Health in Czecho-Slovakia, which was set up on the formation of the Republic, has control of physical education as well as of public health proper. Physical education is compulsory both for males and females—for males up to 21, when they enter military service—and the provision of building and equipment for this purpose is incumbent upon every locality. One of the visits paid by the delegates was to the Dartford Physical Training College, and it is hoped that teachers of physical training in Czecho-Slovakia may be sent to Dartford to complete their studies. Another thing which is compulsory in Czecho-Slovakia is a triple vaccination against small-pox—in infancy, at 7 years of age, and on leaving school. In the State budget for 1921 the amount allocated for public health is 80 million krona, or about 1 per cent. of the whole budget; this relates only to the central administration, and the expenditure of the local authorities, which are charged with the upkeep of most of the hospitals, brings up the amount to about four times as much.

CANCER MORTALITY.

THE recent report of the Registrar-General shows that there was no material change in the rate of mortality from cancer during 1919. The deaths ascribed to cancer during that year numbered 42,144; the numbers for both sexes (18,723 males and 23,421 females) were higher than any previously recorded. In 1909 the total was 34,053 (14,263 males and 19,790 females). The increase has been in cases returned as carcinoma or as cancer. The sarcoma returns

have been almost stationary for the last few years. During the war it was not possible to take into account the whole male population, and the figures showed a very high mortality for males aged 15 to 45. It was suspected that this rise was artificial, being due to the rejection of sufferers unfit for military service. This suspicion is now confirmed by the return with demobilization of male mortality at ages 15 to 45 to its pre-war level; it was 179 per million in 1911-14, and 178 in 1919. With one exception (70 to 75) all the higher ages show an increase over 1918, so that the standardized total rate for males has increased from the comparable figure for 1918 (which was 912) to 943 in 1919. No such general increase in age group mortalities applies to females, and although their crude rate has increased appreciably their standardized rate remains, as in 1918, a trifle lower than before the war. The increase in the crude rate must be due to the rapid diminution of the proportion in the population of the young, whose mortality is very slight. There has been no real fall in the total rates of persons of both sexes; they are a little higher than in 1911-14. Tables showing the organs attacked in fatal cases of cancer are given; their principal features are very much the same as for many years past. It is strange, and as far as we are aware unexplained, that while the mortality of females from cancer of the upper portion of the alimentary canal—namely, the part above the stomach—is a small fraction only of that of males, yet females suffer to about the same extent from cancer of the stomach and more from intestinal cancer; 1,329 cases of cancer of the oesophagus are recorded in males, against 376 in females. Cancer of the rectum also is a good deal more frequent in males than in females; so also is cancer of the lip, tongue, mouth, and jaw. The excess of cancer mortality in the female sex is dependent upon diseases of the breast and generative organs, the number of females dying from cancer of these organs being 9,309, as compared with 903 males. If deaths from these causes be excluded in both sexes the deaths of females are reduced from 23,421 to 14,112, and those of males only from 18,723 to 17,820. Tables giving the site of fatal cancer in relation to age and sex appear to show that in both sexes the age of greatest mortality is 55 to 75, and, with few exceptions, in all the organs enumerated. The number of deaths attributed to tumours not cancerous, or not ascertained to be cancer, was 2,117; of these, 975 were due to tumours ascertained to be not malignant. Among these were 313 uterine tumours, including 242 fibroid tumours, and 273 ovarian tumours, of which 216 were cystic. Of the remaining 1,142 cases of undetermined nature 783 were cerebral tumour; in the large majority of such cases the nature of the tumour was not stated.

SCHOOL PUNISHMENTS

CRANING on the hand as a school punishment was generally condemned at a meeting of the Medical Officers of Schools Association on February 15th. The occasion was a paper by Dr. E. H. T. Nash, who had elicited expressions of opinion from other medical officers of schools by circulating a list of questions. Chastisement in school is most commonly administered by means of the cane, the birch, and, in Scotland, the tawse—a leather strap with a fringe-like end. Occasionally Dr. Nash has found a flat or round ruler, or even a fives bat, employed. The cane, which is the instrument most generally employed in State-provided schools, may inflict great pain and cause much bruising; it is exceeded in these respects only by the ash stick. The birch, still the approved instrument in many public schools, stings severely at the time, but the effect is more transient and the bruising less marked. The fives bat and the flat ruler do not cause undue pain unless brought down on their narrow edge, but the round ruler should be put out of court altogether. As for the site of application, Dr. Nash insisted that the buttocks are much safer and more effective than the hand; thanks to the strength of the gluteal muscles, it is all but impossible to do serious

damage unless there is actual breach of the skin. Dr. Nash had not come across a single instance of damage through the application of the rod to the buttocks; the hind part of the thigh, however, is very tender, and again, if the punishment is inflicted higher in the back, there is danger of injuring a rib. Boxing a child's ears is to be unhesitatingly condemned, although it is true that few cases of rupture of the tympanum have been recorded. Dr. Nash said that he had seen grave damage done by the use of the cane on the hand—in one case such as to impair musical ability, at least during school age. With one exception, all who had replied to his questions condemned caning on the hand; one officer stigmatized it as a barbarous custom. It is continued on account of the objection of parents to the caning of their boys on the buttocks, which is considered derogatory. Caning on the hand, Dr. Nash contended, should be ruled out from school punishments, on medical grounds, but the use of the tawse on the hand might be permitted. With regard to other kinds of punishment, Dr. Nash held, as did other speakers, that so important a part of the physical education as drill ought not to be associated in a lad's mind with the idea of penalty.

MEDICAL EDUCATION IN CHINA.

Two hundred years ago medical science in China was perhaps not far behind that of any other country of the world, but since that time, owing to the absence of hospitals and medical colleges, no progress has been made. Western medicine was introduced into China a hundred years ago by Colledge, a surgeon of the East India Company, and during the past century a large number of mission hospitals were opened in connexion with the missionary effort that is carried on in all parts of the country. These hospitals met with marked success, but it was not until 1881 that the first Chinese medical college was established at Tientsin; six years later a second medical college for Chinese students was founded at Hong Kong, and other medical schools gradually came into existence. The first step in the development of medical education in China consisted in the gathering together of small groups of student assistants at various centres where there were active mission hospitals. These students attended such classes as the busy practitioner was able to give them, but the training that they obtained was chiefly of a practical nature, and laboratory classes were almost unknown. The next step was the establishment of small union medical colleges at the chief cities by the co-operation of various missions; these colleges were sparsely equipped, and all were undermanned, but in them continuous instruction was made possible, and regular laboratory work of a limited character was also instituted. It was by the amalgamation of three of these colleges that the present flourishing school of medicine of the Shantung Christian University was formed. In the year 1915 the Rockefeller Foundation, acting on the report of an influential commission which had visited the country, established a special board for the purpose of assisting medical education in China. This board took over the Peking Union Medical College by arrangement with the London Missionary Society, and reorganized it, making the English language the medium of instruction. The three junior classes of students were transferred to the school of medicine of the Shantung Christian University at Tsinan, in the support of which the Rockefeller Foundation assisted, and where teaching is conducted in the Chinese language. The training of Chinese nurses is being carried on at a modern hospital of over a hundred beds at Tsinan, along with the training of the Chinese medical students; and a nurses' association has been formed, which has done much to fix the status of its members in the estimation of the people. At the Royal Society of Medicine, on February 21st, Mr. Harold Balme, Dean of the Faculty of Medicine of the Shantung Christian Univer-

sity, described to a meeting of members of the medical profession (see p. 303) the development and the present needs of medical education in China. The audience were gratified to learn of the sympathetic attitude which the present Chinese Government has adopted towards the development of education and of medical science in general. The members of the medical profession in Great Britain can help the cause of medical education in China by making themselves acquainted with the facts, by recruiting suitable men for the various posts which become vacant, by obtaining financial support for the project, and by the personal interest which they could show in Chinese graduates visiting this country, more particularly in the provision of post-graduate facilities.

DANGERS OF THE DOMESTIC GAS SUPPLY.

Two committees have recently been set up by the Board of Trade: one to consider the question of the limitation of carbon monoxide content in town gas, and the other to consider that of "inerts"—that is, incombustible constituents. At the first sitting of the former committee, on February 10th, evidence was given by Dr. J. S. Haldane, who said that the poisonous action of illuminating gas was entirely due to the carbon monoxide (CO) it contained. The lowest proportion which would in time produce nausea and headache and other symptoms was about 0.2 per cent., but in the course of some experiments he had found himself able to endure up to 0.6 per cent. without symptoms, as a result of getting acclimatized. When pure coal gas was distributed the risk of poisoning was negligible, but when carburetted water gas, containing about four times as much CO as coal gas, was supplied the risk went up about sixty-fold. The ratio of risk from CO increased out of all proportion to the increase in its percentage. The chief danger was due to burners turned on accidentally in bedrooms. He had allowed pure coal gas, containing about 7 per cent. CO, to escape in a room of about 1,000 cubic feet space, at the rate of about 40 or 50 cubic feet of gas an hour, and found it almost impossible to get a poisonous atmosphere at sleeping level; the gas tended to go to the roof, and only descended in small proportions. But a poisonous atmosphere was readily produced when the CO in the gas was increased three or four times—say to 20 per cent. In a room of the size just mentioned the maximum final percentage of CO in the air with gas containing various proportions of CO would be as follows: In gas containing 5 per cent. CO the maximum final percentage of CO in the air was 0.05 per cent., in 10 per cent. it was 0.09 per cent., in 15 per cent. it was 0.13 per cent., and in 20 per cent. 0.18 per cent. The lowest proportion of CO in the air which would endanger life within about twelve hours was, according to the susceptibility of the person, from 0.15 to 0.3 per cent. Dr. Haldane's suggestion was that a definite maximum of 20 per cent. CO in illuminating gas for domestic purposes should be laid down. At a previous inquiry twenty years ago he had advocated 12 per cent., but distribution of gas and pattern of burners had improved in the meantime. The other witnesses at the first sitting were two chief engineers and a chief chemist of gas undertakings. All three were strongly against the fixing of any limit for CO. One of them, representing the Gas Light and Coke Company, stated that, taking the ten years during which the largest quantity of carburetted water gas had been supplied by his company, 15 deaths had occurred in the area from accidental inhalation; in 3 other cases of sick people death had been accelerated by gas, and there were 11 cases of gas suicide. A Liverpool gas engineer gave figures for the last twenty years, during which there had been 38 fatalities attributed to accidental gas poisoning and a further 16 due to suicide. Of the 38 cases 22 were in districts supplied with gas containing less than 12 per cent. of CO and 16 in districts supplied with gas containing a higher

proportion. Medical opinion will, we believe, look upon arguments of this nature with suspicion. Carbon monoxide is an extremely dangerous gas, since it attacks the haemoglobin of the blood and is only slowly and with difficulty expelled. Moreover, being colourless and odourless, its presence in a room tends to mask an escape of coal gas, while greatly adding to its dangers.

THE BIRTH-RATE COMMISSION ON VENEREAL DISEASE.

THE voluntary organization known as the National Birth-rate Commission, which began its labours in 1910, and has already issued reports on the declining birth rate and problems of population and parenthood, has now completed a report on the prevention of venereal disease, which will be published by Messrs. Williams and Norgate on February 28th. The witnesses who advised a special committee on venereal disease of the Birth-rate Commission numbered over a score, and included physicians, surgeons, and venereal specialists of both sexes, medical officers of health, social workers and ministers of religion, medical officers of the British and American armies, representatives of the Ministry of Health, and of the two well known societies with somewhat conflicting views upon the problem of venereal disease. The conclusions reached are summed up in two sections, one on the medical aspects of the subject and the other on the moral aspects. The committee, although realizing that chastity is the best safeguard against the spread of venereal disease, recognizes that a large number of persons, male and female, will not respond to such moral appeals. It believes, therefore, on grounds of both national and individual welfare, that it is of importance to prevent by all legitimate means the development of disease in those who expose themselves to the risk of infection. It considers that some method of disinfection must be carried out as soon as possible after sexual intercourse; but the results in preventing the development of disease depend largely, it is stated, on the interval of time elapsing and the care with which the disinfecting process is carried out. In this the report appears to agree with the policy of the Society for the Prevention of Venereal Disease in recommending some form of "early self-disinfection." The report points out that the Act at present in force prevents individuals from obtaining the necessary antiseptics from chemists, and it recommends that chemists should be allowed to sell disinfectants with instructions. The committee thinks that the Ministry of Health should, through local health authorities, draw public attention to the menace to national health and welfare arising from venereal disease; and while it recommends the continuance of the early treatment centres at Manchester and elsewhere for a time, it is of opinion that it is undesirable to provide further expensive ablation centres before it has been definitely ascertained that men are unable by other means to disinfect themselves efficiently. In dealing with the relation of the moral to the medical aspects of the problem the view is expressed that a medical man in dealing with these diseases, or in proposing means for their prevention, cannot divest himself of his responsibility as a moral agent dealing with patients who are also moral agents. The moral appeal by its very nature must be the more enduring, and it is recommended that, in view of the serious situation, parents, teachers, and ministers of religion, social reformers, and medical practitioners, legislators and administrators, should combine in a national effort to assert the moral obligation of chastity, the sanctity of marriage and parenthood, and the equality of the moral standard for the two sexes.

PHYSIOLOGY AT SOUTH KENSINGTON.

THE Faculty of Medicine is considering this week the proposal of the Senate of the University of London to close the University Physiological Laboratory at the end

of July, in order to provide university headquarters with more extensive accommodation for clerks, and, as has already been stated, the subject will be before the Faculty of Science—that most directly concerned—next week. It is probable that both faculties will take the view that the suggested closure would be a grave injury to the advancement of medical science, and recommend that the laboratory should be continued as a valuable part of the work of the University. A correspondent has called our attention to a memorandum written by the Prince Consort in August, 1851, at the end of his tenure of the chairmanship of the Exhibition Commission of that year. The memorandum mentions that ground was then available in Kensington Gore, and suggested that it should be purchased and four institutions erected on it—the first for metallurgy, metallurgical chemistry, and animal and vegetable physiology; the second embracing polytechnic science, with its subdivisions; the third a school of design and chemistry as applied to manufactures; and the fourth devoted to architecture, antiquities, and sculpture. In the following year ninety acres were acquired at a cost of £342,500, upon which now stands the Albert Hall, the Royal College of Music, the Imperial Institute, the Imperial College of Science and Technology, the Natural History Museum, and other educational buildings; thus, as our correspondent points out, more than realizing in the material, if not in the spirit, the intention expressed by the Prince Consort in 1851. It will be observed, first, that a site larger either than that at Holland Park or Bloomsbury was acquired for purposes of higher education and research seventy years ago, and secondly, that physiology was among the subjects of research and instruction to which it was at that time proposed to devote the site.

A WAR SECTION OF THE WELLCOME MUSEUM.

A SECTION illustrating naval and military medical service during the war has been added to the Wellcome Historical Medical Museum. It is not of great dimensions, but is an assembly of some typical exhibits, which may yet be enlarged by the loan of trophies by ex-officers and others. Ambulance arrangements are the subject of a gallery of photographs so selected and placed as to tell a story instead of bewildering the visitor with a jumble of impressions. Every kind of transport for the wounded seems to be included in these pictures, from the well-equipped hospital train to the mule *travois* of the Balkans and the camel caolet of further east. Naval ambulance, which was fully described in a series of articles published in the *BRITISH MEDICAL JOURNAL* of April 28th, 1917, is illustrated by photographs, models, and an example of the slung cot used both ashore and afloat. A number of contemporary drawings and paintings have found a home in Wigmore Street. In contrast to Matania's sketch of the aerial transport of the wounded on the Italian (Alpine) front, there are the post-cards coloured by a R.A.M.C. sergeant with the help of Condy's fluid and tincture of iodine. A collection of orthopaedic appliances is a feature of the section. The curator, Mr. C. J. S. Thompson, is justifiably proud of having secured a number of articles in papier-mâché, leather, and common canvas, which were worked by the skilled fingers of the English ladies in the Palazzo Centurione in Rome. Various protective devices are on view, including smoke helmets, anti-gas apparatus with respirators, the masks and gloves used to guard against the back-flash of big guns, and various kinds of goggles; one pair of these, as a protection against shell splinters, is on the principle of the Eskimo snow spectacles, with the narrowest possible slits for vision. Some of the exhibits go back earlier than the recent war. The telephone probe is supposed to have originated with Graham Bell, and to have been first applied in this country by Mackenzie Davidson. But it was anticipated to some extent by Sir Thomas Longmore, and the instrument which he devised in the middle of the nine-

teenth century is here on exhibition; it is a bullet-detector in which a compass is employed to signify by the deflection of its needle when contact is made between the dependent probe and the foreign body. Another exhibit consists of field dressings, including the compressed bandage used in the Crimean war, the first antiseptic wound-pad, dated 1883, and the first field-dressing served out in 1914; also a bandage prepared from the bark of a tree by the Germans in East Africa. The contents of a German field valise are well worth study for the compactness and ingenuity of the arrangements. In the surgical instrument case the distinctive outline of each instrument is marked on the outside of the pocket into which it is to go, so that there may be no mistake in replacement. One case is filled with hospital equipment taken from a German cruiser in 1918. One of the U-boats has yielded up to the Wellcome Museum its oxygen cylinders and attachments. Lastly, there is a replica, in gilded copper, of the mace presented to the American College of Surgeons by the consulting surgeons of the British armies in memory of mutual work and good-fellowship in the great war.¹ It has been finished by hand by Mr. Omar Ramsden, the gifted worker of the original. The Curator is indebted to Surgeon Captain M. Knapp, R.N., and Lieut.-Colonel Brereton for their kind assistance in procuring and describing many of the exhibits.

THE POSITION OF THE FINE CHEMICAL INDUSTRY.

THE Association of British Chemical Manufacturers is circulating a memorandum on the present position of the fine chemical industry. The facts and arguments are on similar lines to those in the pamphlet issued from the Society of Chemical Industry already noticed in these columns. It is stated that British chemists, as a result of the stimulus imparted by the war, have brought the manufacture of the chemicals used in research and in photography, and of certain synthetic perfumes and essences, to the verge of commercial success, while the manufacture of drugs has made immense strides, and would have made greater had not the Order in Council prohibiting the importation of drugs been set aside by the Sankey judgement. The hope is expressed that the Key Industries Bill, which has been promised as a Government measure of the new session, may do for fine chemicals what has already been done for dyestuffs by the Act recently passed; that is to say, that some protection may be granted to the manufacturers of fine chemicals until they have consolidated a position which has been hardly won and which is still precarious. The insecurity arises from the fact that there are circumstances, including the great priority of organization, and also the present state of the exchanges, which favour the German laboratories. The national importance of this industry in peace and war is pointed out, and it is also stated that, excluding coal-mining, the fine chemical industry yields the highest net value of output per person employed.

THE WAR FINANCE OF THE RED CROSS AND ST. JOHN.

THE accounts of the Joint War Finance Committee of the British Red Cross Society and the Order of St. John from October 20th, 1918, to June 30th, 1920, have been issued, together with a final report on the financial operations of the Committee, and a summary of accounts from October 20th, 1914, to June 30th, 1920. The latter will be included in a detailed record of the whole war work of the joint organization which has been in preparation since the Armistice, and will be published shortly. The joint organization of the two corporations, set up for the purposes of the war, was placed under the financial control of a Finance Committee, which was presided over by Sir Robert Hudson, G.B.E., and annual accounts were rendered throughout the war. Some idea of the

magnitude of the financial work which fell to the Finance Committee will be gained from the fact that it has had to account for receipts amounting to £21,885,035 and expenditure £20,058,355. Of the receipts £16,510,023 were received in money from the public and £1,027,280 in kind; Government grants, interest, and various receipts from other bodies make up the total. The chief items of expenditure were £2,053,501 for the transport of wounded; £2,928,367 for hospitals, not including local expenditure on the auxiliary home hospitals; £5,017,285 for stores; £5,147,876 for prisoners of war, and £2,717,927 for post-war schemes for sick and disabled ex-service men and kindred objects. These last services were provided by the Red Cross and St. John Act of 1918, which governs the disposal of any surplus. The surplus on June 30th last amounted to £1,826,680. Claims upon the surplus on behalf of the wounded will continue to be received for a long time to come, and the Committee in its report foreshadows the development of a scheme throughout the country for the benefit of disabled ex-service men. Copies of the accounts can be obtained from the inquiry office 19, Berkeley Street, W.1., at the price of 1s. each.

THE Morison Lectures will be delivered before the Royal College of Physicians of Edinburgh by Sir Frederick Mott, F.R.S., on Monday, Wednesday and Friday, March 7th, 9th, and 11th, at 5 p.m. on each day. The subject of the course is "The Psychopathology of Puberty and Adolescence." The lectures will be illustrated by drawings and lantern slides. The first lecture will deal with the reproductive organs in relation to the endocrine glands and the autonomic nervous system; the second and third with the pathology of dementia præcox.

A NEW edition of Liddell and Scott's *Greek Lexicon* has been on the stocks since October, 1911, when Mr. Henry Stuart Jones was appointed editor. He has had the assistance of many specialists and a large number of voluntary readers who have undertaken to read for the dictionary. Among the specialists who have given their help are Sir W. Thiselton-Dyer, F.R.S., who has an extensive acquaintance with Greek botanical terms, and Dr. E. T. Withington of Oxford, who has read the whole of the voluminous literature of Greek medicine, with the result that practically all the articles on medical terms have been rewritten and considerable additions have been made to the vocabulary of the subject. Recently Mr. Roderick Mackenzie has been appointed assistant editor, and the Secretary to the Delegates of the Oxford University Press has announced that it is hoped shortly to begin the printing. It is proposed to issue the new edition in ten parts of about 200 pages each, price 10s. 6d. a part, or a subscription price of four guineas. As the total outlay, it is estimated, will approach £20,000, it is unlikely that the sales will total this amount.

Medical Notes in Parliament.

Dangerous Drugs: Draft Regulations.

SIR THOMAS BRAMSDON asked the Home Secretary, on February 17th, if, in formulating the draft regulations for the sale, prescribing, dispensing, and distribution of cocaine, ecgonine, morphine, heroine, and opium (medicinal), the British Medical Association, which represented and spoke for over 22,000 medical men, were not consulted; if he were aware that the proposed draft regulations were regarded by medical practitioners throughout the kingdom as impracticable; that if Clause 13 of the proposed regulations were strictly carried out it would be impossible for medical men to obtain those drugs from wholesale chemists by train or through the post; and that, however urgently needed, it would be impossible for a doctor to obtain these drugs by telephone message; and if he were prepared to submit the regulations for consideration and amendment to a committee composed of representatives of the Home Office, the Ministry of Health, the British Medical Association, and the Pharmaceutical Society, as well as of the

¹ BRITISH MEDICAL JOURNAL, October 16th, 1920, p. 597.

Milk and Dairies Bill.—In answer to Mr. Swan, Dr. Addison said that it was not at present proposed to reintroduce the Milk and Dairies Bill during the present session.

ASSOCIATION OF PUBLIC VACCINATORS.

ANNUAL MEETING.

The annual meeting of the Association of Public Vaccinators of England and Wales was held at the Queen's Hotel, Leeds, on January 28th, when Dr. C. J. PALMER (Mansfield) was in the chair. The report and balance sheet were approved and adopted. It was noted with satisfaction that the circular letter recently addressed to boards of guardians had in some cases been effective in securing an increase of fees for vaccination. The officers and council were elected for the ensuing year. Votes of thanks were accorded the retiring president (Dr. C. J. Palmer), the editorial secretary (Dr. A. Drury), and the organizing secretary (Mr. F. A. Briggs), for their valuable help during the past year. Dr. A. T. BACON (Leeds) was elected president, and received a hearty welcome on taking the chair vacated by the retiring president.

At the conclusion of the formal business a very interesting address was given by Dr. W. McCONNEL WANKLYN on "The abolition of small-pox." Dr. Wanklyn's experience in dealing with small-pox outbreaks lent much importance to his address. He observed at the outset that his aim was to keep out small-pox, which was identical with the aim of vaccinators. The true policy and objective, he considered, was to attack small-pox, throw it out of the country, and keep it out. The year 1904 might be looked upon as a landmark in the control of small-pox in London. Thousands of lives and vast sums of money had been saved by the system then adopted, whereby suspicious cases could be seen at their homes at the very outset in consultation with the medical attendant. This led to the early recognition of cases. Early diagnosis was of the greatest importance. Dr. Wanklyn then depicted the natural history of small-pox. Recent prevalence showed that, though the periods of comparative quietness had been longer than formerly, there was still a definite risk of an epidemic. The risk was increasing, since infection was frequently imported and the susceptibility of the population was increasing. Paying a high tribute to the courage and bravery of the men of the Notts, Derby, and Leicester regiments, Dr. Wanklyn said he found himself attacked to a division largely composed of these men during the war, practically all of whom were antivaccinators and opposed to inoculation against enteric. He talked to the men, gave them lectures, and found them willing to drop their objections; many thousands were vaccinated, and 95 per cent. of the division were inoculated. He urged the importance of instructing the laity. Every human being born was susceptible to small-pox. There was a world prevalence of small-pox at the present time, and all the trade routes lead to this country. A chart showed its prevalence in various parts of Europe, India, Japan, United States, Egypt, Africa, and Brazil. The cost of small-pox, which was enormous, must be reduced at once by the proper adoption of preventive measures, which were outlined. There was a possibility any time now of an epidemic of small-pox on a big scale. Once begun and established, the cost to the country of such an epidemic would amount to many millions of pounds. It would be calamitous to life, to business, to efficiency, to finance, and general health administration. It was our duty to do all things possible to prevent such a calamity.

ANNUAL DINNER.

In the evening the first annual dinner since 1914 was held, and there was a good attendance of members and friends. Dr. A. E. CORR (London) proposed "The President," to which Dr. BACON replied. "Our Guests" was proposed by Dr. DRURY (Halifax). The replies were given by Dr. J. R. KAYE (County Medical Officer, West Riding), Professor J. KIR JARVIS (Dean of the Faculty and Professor of Anatomy, Leeds University), and Dr. W. McCONNEL (London). A most enjoyable entertainment was provided; Miss Marjorie Abercrombie gave songs, and Miss Margaret G. Drury a recital of serious and humorous selections.

A CONGRESS of school hygiene will be held in Paris next April under the presidency of Dr. Mery. Dr. Dufestel has been appointed vice-president and Drs. Genevriev and Mathé secretaries.

England and Wales.

LEICESTER PUBLIC MEDICAL SERVICE.

The report of the Leicester Public Medical Service for 1920 has been issued and records the continued success of its work, the rate per capita paid to "acting members" of the service showing a substantial advance. The arrangement has been continued whereby free medical treatment is provided for the uninsured blind of Leicester, as has also been the co-operation with the Education Committee for carrying on the school clinic work at the central dispensary.

The annual report of the Leicester Subdivision of the Union of Medical Practitioners shows that the scheme of collective locumtenencies for the summer holidays, which was inaugurated during 1919, was successfully continued during the summer of 1920. Twenty doctors availed themselves of the facilities afforded, contributing to a pool which was distributed among the practitioners who attended patients under the scheme. Alterations have been made in the Public Medical Service rooms in order that they might be used as a club for the medical men of Leicester and the county. The rooms have been furnished, gifts of furniture, books, and pictures having been received, and billiard, reading, and writing rooms have been provided. The club is now called the "Leicester Medical Club," and is conducted by a committee, of which Dr. C. C. Binns is honorary secretary and treasurer.

SHEFFIELD EDINBURGH UNIVERSITY CLUB DINNER.

On Saturday, February 19th, the Sheffield Edinburgh University Club held its tenth annual dinner, the first since 1914. Dr. G. Scott Davidson, president of the club, was in the chair, the croquiers being Drs. Blyth, Murray, and Anderson. The guest of the evening was Professor Caird of Edinburgh, and a company of just 100 members and guests was present to meet him. The toast of the Alma Mater was given by Dr. Yates in a charming speech reminiscent of his student days in the faculties of Arts and Medicine at Edinburgh. Professor Caird, in his reply, told delightful tales of those far-away days of the early seventies when he himself was a student. He was especially happy in his memories of "Old Woody Fibre" (Professor Hutton Balfour), "Dismal Jimmy" (Professor Spence), Pat. Watson, and Joe Bell. His story of the workman from the Forth Bridge who entered Bell's clinic carrying in his pocket a handkerchief which had been slyly soaked in ammoniacal urine by a student, thereby causing Joe Bell to make a wrong diagnosis for once, was greatly appreciated. He referred to the overcrowded condition of the university at the present time, and to the probability of an early rise in the fees at the university. The toast of the guests was given by Dr. Peck and responded to by Professor Leathes and Colonel Connell.

CENTRAL MIDWIVES BOARD.

The Central Midwives Board met on Thursday, February 17th. A special meeting was held first, at which five midwives were struck off the roll.

At the ordinary monthly meeting, when Sir Francis Champneys was in the chair, in reply to a letter from Dr. Comyns Berkeley, a minute was adopted stating that the Board had given very careful consideration to the request from the majority of its examiners for an increase in examination fees; but having regard to the fees paid by other examining bodies for work of a similar nature, and to the fact that the amount of the fees payable by candidates is limited by statute, the Board regretted that it did not see its way to grant an increase at the present time. Should the Board at some future time be enabled to increase the fees payable by candidates, it would reconsider the question of increasing the fees of its examiners. An application from the authorities of the Eden Hospital, Calcutta, that the hospital might again be approved as a training school was granted. In reply to an inquiry as to the jurisdiction of a local supervising authority to inquire into the conduct of a midwife when acting as a monthly nurse, the Board replied that the authority had jurisdiction to consider a charge of misconduct (other than professional misconduct), if such misconduct tended to

unfit the midwife for the discharge of her duties as a midwife; this jurisdiction was not ousted by the fact that when guilty of such misconduct the midwife was not acting as either a midwife or as a monthly nurse. In the opinion of the Board, however, the Midwives Acts confer no jurisdiction upon either the Central Midwives Board or the local supervising authorities to investigate charges of malpractice, negligence or professional misconduct preferred against a midwife when acting as a monthly nurse, unless her conduct constitutes a violation of Rule E. 6 of the Board's rules.

Scotland.

EDINBURGH UNIVERSITY CHEMICAL LABORATORIES.

ALTHOUGH it is only a year since the work of building the chemical laboratories of the Edinburgh University at Liberton was commenced some of the rooms are already in occupation. Apart from the front portion of the building where the administrative offices and the library are situated, and which is in two stories, the building is of one story, and all the laboratories are lighted from the roof.

At present only the advanced chemistry students are accommodated at Liberton, but eventually when the buildings are completed the whole of the chemistry department of the University will be transferred to this site. At a later period buildings will be erected there to accommodate the Geology and Zoology Departments. There is a long central corridor from which the several laboratories open on one side. The buildings on the other side have yet to be erected. The laboratories are economically but fully equipped. There is ample bench accommodation for each student. Opposite his seat and at the level of his head is a draught hole which draws fumes into a system of air ducts. Leading off a long corridor parallel to the main corridor are research rooms, where advanced research students may carry on their individual work. The laboratories are under the supervision of Professor Sir James Walker.

GLASGOW ROYAL ASYLUM.

At the annual meeting on February 17th, of contributors to the Glasgow Royal Asylum, Dr. Oswald, physician superintendent, in a written review of the year's work, pointed out that a preponderance of female over male admissions, was, as in the previous year, a striking and remarkable feature. The only possible explanation seemed to lie in the fact that women nowadays were taking a much more active part than formerly in community life, in consequence of which a much greater strain was thrown on them, with the not unnatural result that there were a greater number of so-called nervous and mental breakdowns. It seemed, too, as though a contributory factor might be the reaction following the stress of war years. Dr. Henderson, assistant superintendent, said that the great difficulty in regard to mental treatment was that they could not get the patient to seek medical advice early enough. He thought that much good might be done if out-patient mental clinics were established, just as we had out-patient clinics for physical diseases. He urged also the desirability of occupational departments associated with mental hospitals, but separated from the wards of the institution.

CARNEGIE UNIVERSITIES TRUST.

The annual meeting of the Carnegie Trust for the Universities of Scotland was held in a committee-room of the House of Lords, on February 9th, with Lord Balfour of Burleigh in the chair. Lord Balfour said that the principal event of last year was the allocation of grants for the quinquennial period of 1920-25. In addition to the £200,000 from income, it had been resolved to allocate from the reserve fund £49,000. The explanation of this was that during the war the students at the universities were fewer, and therefore the trustees saved on the payment of fees. It would have been absurd to save that money and put it to the reserve, when many of the same students were coming back after the war and wanted it. The trustees thought it right, as a temporary measure, to take it out of the reserve fund, and give it to them to pay their fees. Under the research scheme it had been agreed that as an experiment for a period of three years the

following annual grants be offered to the universities to be spent in payment of half the salaries of persons engaged as part-time assistants or lecturers on condition that they devoted not less than half their time to research, and that the universities should contribute the other half of the salaries from other sources—Glasgow and Edinburgh £1,000 each, St. Andrews and Aberdeen £800 each. It was hoped that much good to the universities would result from this combination of teaching and research, and the scheme had been well received by the universities. Although the amount available for assistance to students was now fully £50,000, there was a deficit of £8,533 for 1919-20. The universities were now increasing their tuition fees, and as a result the poor student would be poorer than ever. Thus the difficulties were very great. For many years the trustees had been able to pay all eligible applicants the whole of their class fees, but in 1911-12 they had had to have an allowance system, because the income would not cover the whole of the fees, and since then the trustees had been paying only a part of the fees. The situation would be further changed in the current year owing to the increase in tuition fees.

The discussion, in which Lord Haldane, Lord Sands, and others took part, centred chiefly in the problem of allocating assistance to the students. It was agreed that steps must be taken to eliminate from the beneficiaries of the fund those applicants whose circumstances were such as to render assistance unnecessary. Proposals were made for strengthening the declaration made by applicants and for an inquiry into individual circumstances. The suggestions were discussed, but a decision will not be reached until the alternatives have been further considered in the light of the views expressed by university authorities and others interested.

EAST OF SCOTLAND OVERSEAS MEDICAL CLUB.

The second annual dinner of the East of Scotland Overseas Medical Club was held in Edinburgh on February 18th, when Professor Francis Boyd, C.B., C.M.G., president, was in the chair. There was a large gathering, many from distant parts of Scotland. The guests included Lieut.-General Sir Francis Davies, K.C.B., G.O.C. Scottish Command, Surgeon Rear-Admiral J. Stenhouse, R.N., Colonel Browne-Mason, D.S.O., D.D.M.S. Scottish Command, Mr. T. Kay, D.S.O., M.D., president of the West of Scotland Foreign Service Medical Club. Apologies were received from Sir John Goodwin, K.C.B., D.G., A.M.S., Colonel P. S. Lelean, C.B., C.M.G., and others. Amongst those present were Drs. T. F. Dewar, C.B., Henry Wade, C.M.G., D.S.O., Morrison McIntosh, C.M.G., C. E. Douglas (Cupar), R. A. Fleming, W. A. Taylor (Perth), William Haig, D.S.O. (Crieff), James Young, D.S.O., David Lees, D.S.O., J. F. Crombie, D.S.O., George Rae Gibson, D.S.O., Pirie Watson, O.B.E., D. P. D. Wilkie, O.B.E., J. W. Mackenzie, O.B.E. (Inverness), A. L. S. Tuke, M.C. (Dunfermline), W. T. Gardiner, M.C., Stewart Hodgson, M.C. The toast of "The Imperial Forces" was proposed by Dr. C. E. Douglas of Cupar, who recalled the time when this toast embraced the Navy, the Army, and the Volunteer Forces, and when the mention of the last was apt to be received with a smile. Those times had changed, and nowadays this toast might be considered as embracing within its compass the whole nation. Lieut.-General Sir Francis Davies, who responded, referred to the services rendered by the medical profession during the past war, and especially to the way in which the civil practitioner had forsaken everything to dedicate his services to his country. The regular medical branch of the Army was greatly the better for his inclusion. Whilst he was at the War Office he was greatly impressed by the many striking instances of gallantry shown by medical men which came before him for recognition. The President proposed "The Club," and in doing so referred to its thriving state. It possessed about 200 members, all of them medical men who had served overseas during the past war. Amongst its many advantages the greatest was that of bringing together men who had worked together on the field of battle and in overseas hospitals. The toast of "The President" was proposed by Dr. George Rae Gibson. Dr. C. E. Douglas of Cupar was elected president-elect, and Drs. W. T. Gardiner, M.C., and Pirie Watson, O.B.E., were elected to the committee in place of T. F. Dewar, C.B., and Henry Wade, C.M.G., D.S.O. The secretary is Dr. James Young, D.S.O., Edinburgh.

Ireland.

REPORTS ON WOUNDED IN DUBLIN HOSPITALS.

On behalf of certain Fellows and Licentiates of the Royal College of Surgeons, Ireland, affected by the military Order recently issued requiring them to furnish daily particulars of wounded persons under their care in hospital, a communication has been addressed to the Council of the Royal College stating that the Licentiates and Fellows of the College and the Irish profession generally would be glad for an expression of opinion by the Council regarding the military Order referred to and asking the Council to make representations to the military authority to have the Order revoked. Fellows and Licentiates of the College, and other members of the profession, have expressed strong opinions with regard to the breach of professional confidence involved in giving effect to the military Order, and for this and other reasons feel serious objection to furnishing the information required by the military authority. That authority, however, has stated that failure to comply with the Order will render the medical practitioners concerned liable to be proceeded against for an offence against the Restoration of Order in Ireland Regulations. The republican army in Ireland have countered the military Order by intimating to the doctors concerned that should they obey the Order such doctors will be treated as spies.

It was also brought to the notice of the Council that Poor Law medical officers, a large proportion of whom are Fellows and Licentiates of the Irish College, have not received any portion of their salaries, in some cases, for almost twelve months. At first sight it may seem that this condition of affairs is due to the deadlock between the Local Government Board and the local authorities, and that the trouble could be got over if the local bodies would only administer the necessary statutes, including the Malicious Injuries Amendment Act. These Acts, however, provide that all awards for malicious injuries, including those committed by the Crown forces, shall have first claim on the funds of the local authorities. In effect, this means that the entire salaries of the Poor Law medical officers, in most counties, are set aside in order to meet claims for malicious injuries. The local authorities, assuming they complied with the statutes, are asked to do what is financially impossible—namely, to raise a rate sufficient to meet ordinary expenditure as well as the amount awarded for malicious injuries, which, in many counties, would mean £2,000 rates on a farmer with £100 Poor Law valuation. As long as these conditions exist, there seems to be not the remotest chance that a Poor Law medical officer, in the majority of Irish counties, can receive his salary or any portion of it. Irish health services, under the Medical Charities Acts, would have ceased to be administered six months ago only that the Poor Law medical officers continued to give their services; they did this notwithstanding that, owing mainly to the diversion of health grants to other purposes under the recent special Acts of Parliament already referred to, their salaries were not paid.

The slender resources of the average Poor Law medical officer will not, however, permit him much longer to carry out his work on the present terms. This contingency has already been brought to the notice of the Chief Secretary, who is Minister of Health for Ireland. His reply held out no hope that there was any intention on the part of the Government to alter or amend existing legislation so that a way out of the present difficulty may be found. The result is that fully 30 per cent. out of the 50 per cent. of the population of this country who are dependent for their treatment on the Poor Law medical officers—as such—are at the present moment unprovided for as regards medical treatment. Legislation amending the recent statutes, which are responsible for the diversion of health grants and other funds from the purposes to which they were hitherto applied, is the only remedy if the necessitous one-fourth of the population of Ireland are not to be left without medical treatment of any kind.

ARRESTS OF MEDICAL MEN.

Dr. Thomas F. Higgins, F.R.C.S.I., coroner for Queen's County and medical officer of the St. David's district, has been arrested by the Crown forces; he is over 70 years of age. His son, Dr. T. Higgins, Maryborough, has been

interned for some months without being brought before a court-martial. Dr. Ryan, Wexford, has been transferred from Waterford Gaol for internment in the Kilworth Camp, co. Cork. His wife, Mrs. Ryan, has also been arrested; the reason assigned is that she objected to a military proclamation being posted on one of her windows. The military authorities in many of the southern towns make it a practice to post proclamations on windows, holding the inhabitants responsible in case of their being torn down or effaced.

ACIDAEMIA.

At the meeting of the Ulster Medical Society on February 18th, when the President, Dr. Thomas Houston, O.B.E., occupied the chair, Sir Almoth Wright, K.B.E., C.B., F.R.S., gave an address on the pathology and treatment of acidaemia. He first mentioned a number of instances of acidaemia—a rabbit to which was administered an excess of hydrochloric acid; a guinea pig fed on a specially restricted diet; cases where the body itself produces the acid as in diabetes, and the acidaemia in gas gangrene and in shock. When these were examined it was seen that they could be classified as (1) myogenous and (2) non-myogenous. If a muscle was deprived of its blood supply, lactic acid at once began to collect owing to the deprivation of oxygen; a local acidity was thus produced in the muscle, and this he called "acidosis"; if the blood supply returned, this lactic acid was swept into the circulation and "acidaemia" ensued; the simplest illustration of this was when an artery was ligatured; the same result followed in the application of a tourniquet or of an Esmarch's bandage; it also occurred when an animal was submerged in ice cold water; here the "somatic" circulation failed and the visceral alone remained, there was an asphyxia of muscle. If a heart failed owing to a microbial poison, or if a patient collapsed, as after wounds and exposure, or after a long operation, a similar condition was produced; among the dangers after an anaesthetic was collapse. Different animals were differently affected. Some, as the rabbit, were very susceptible; some, like the cat with its nine lives, were the reverse, no doubt human beings also varied. When a person, collapsed from injury and long exposure to cold, was brought into hospital, if the somatic circulation slowly returned, then the lactic acid was oxidized; but if the heat was brought back rapidly by artificial means and the limbs massaged, the patient was liable to develop acidaemia. A frost-bitten part is rubbed, not heated by applications. In conditions of shock, fluid introduced into the blood vessels escaped with great rapidity, whereas, if it were introduced before the onset of shock it was retained. In shock there was a polycythaemia in the capillaries, due probably to the rapid escape of the fluid, so that the heart had a heavier weight to drive. The essential point in treatment was to prevent the onset of shock—to try to anticipate it. Cohnheim had shown that the blood might be diluted many times in an animal without its rapidly escaping, so that before a long operation with an anaesthetic was attempted the alkalinity of the blood should be tested, and the operation postponed if the result were not satisfactory; then would be the time to prevent the onset of shock; medicinally, sodium lactate should be given. In cases of shock a rapid recovery had been obtained by intravenous injection of an alkali, but these patients were liable to relapse, owing probably to developing acidaemia. Cannon found that cases of gas gangrene and shock had marked acidaemia; the gangrene bacillus did not grow in alkaline muscle, it would not grow in a healthy rabbit, but if a rabbit were killed after inoculation and its body put in an incubator, rapid growth took place so that it became distended with gas. In concluding his lecture Sir Almoth urged the necessity of advancing step by step in our investigations. The *salvus empiricus* was to be avoided by all true scientific followers; they must be content with the *passus scientificus*.

Dr. R. J. Johnstone, F.R.C.S. Eng., proposed a hearty vote of thanks to the lecturer; this was seconded by Dr. J. E. MacIlwaine, and passed by acclamation.

ULSTER MEDICAL SOCIETY.

At the annual dinner of the Ulster Medical Society, held in the Medical Institute, Belfast, on February 17th, when the President, Dr. Thomas Houston, O.B.E., occupied the chair, the chief guest was Sir Almoth Wright.

The toasts were "The King," proposed by the President; "The Lord Mayor and the Corporation of Belfast," proposed by Professor Lindsay, F.R.C.P.Lond., and responded to by the High Sheriff; "Our Guests," proposed by the President, who expressed the great pleasure of the society in seeing Sir Almroth once more amongst them, and their deep obligation to him for stimulating them with his keen scientific mind. He outlined some of Sir Almroth's work in typhoid prevention and, during the great war, in wound sepsis. Sir Almroth, in reply, emphasized the fallaciousness of experience and the necessity of experiment. Dr. Fleming also replied. "The Legal Profession" was given by Dr. J. S. Morrow, and acknowledged by the Recorder of Belfast and the President of the Law Society. "The President" was proposed by Dr. MacIlwaine, and Dr. Houston in his reply said that much of the success and of the excellent arrangements of the dinner were due to the editing honorary secretary, Dr. Robert Marshall, who took Dr. W. W. D. Thomson's place during the prolonged illness of the latter, who, he was glad to say, was now much better. He proposed Dr. Marshall's health, and offered him the thanks of the society. Dr. Marshall replied.

Correspondence.

SURGERY OF BREAST CANCER.

Sir,—Mr. R. H. Parry's demonstration (January 15th, p. 99) of the presence of malignant cells in the supraclavicular glands in five out of six selected cases of breast cancer is a most important fact, since the cases were specially chosen as presenting no clinical signs of supraclavicular infection.

Mr. Parry and I have, by different roads, reached the same conclusion—namely, that no operative method for breast cancer is satisfactory which does not as a routine take steps to counter infection of these glands. It might have been hoped that post-operative x-ray treatment would have proved adequate for the purpose, but experience shows that this is not the case, at any rate with present x-ray methods.

The choice appears to lie between routine removal of the supraclavicular glands as part of the primary operation, as advocated by Mr. R. H. Parry and Mr. Charles A. Morton, and the routine use of buried radium as described in my article. It will not be possible for several years to decide on the relative merits of these two methods, and it is well for the present that both should be practised. Personally, I am hopeful about the buried radium method and intend to adhere to it. In view of the striking shrinkage of obviously enlarged glands which often occurs after its use, it should be competent *a fortiori* to deal with the early microscopic stage of infection. As compared with excision it has the great advantages that it is applicable even in old or enfeebled patients, and that it does not increase shock or appreciably prolong the operation. It is, however, true, as Mr. Parry points out, that the present scarcity of radium restricts the use of the method to centres where it is available in sufficient amounts—say 100 mg.

Unless infection of the anterior mediastinal glands is secondary to infection of the supraclavicular glands, as Mr. Parry believes, both these sets of glands require to be dealt with. Now I have seen recurrence, apparently originating from the anterior mediastinal glands, in cases where no enlarged supraclavicular glands could be felt. Logically, therefore, if the supraclavicular glands are excised it seems to me that the anterior mediastinal glands should also be removed. My adhesion to the buried radium method is partly due to an unwillingness to face such an alarming, though quite possible, extension of the operation. I have cleared the anterior mediastinum in 6 cases. In 4 of these no glands—or only uninfected ones—could be found. In 2 cases infected glands were found, and both these cases subsequently died of recurrence.

Mr. Robert E. Lord's letter of January 22nd asks most pertinent questions as to x-ray dosage, which, however, should be addressed rather to radiologists and physicists than to a surgeon. Questions of quality, as well as quantity, arise. I will only record my impression that I have seen the best results in cases where deep pigmentation of the skin has been secured over a wide area.—I am, etc.,

London, W., Feb. 16th.

W. SAMPSON HANDLEY.

X-RAY RADIATION AND CANCER.

Sir,—A letter from Dr. Reginald Morton in your columns of January 29th stated that, after a recent visit to a Frauenklinik in Bavaria, he came home with the conviction that only spark coils will supply the really hard radiation which is necessary for the successful treatment of deep-seated malignant diseases; that there is only one outfit in this country capable of doing this work; and that a weak dose of x rays will stimulate the growth of malignant cells instead of killing them.

I beg to draw attention to the fact that my firm has persistently advocated the necessity of using spark coils for producing hard rays; that coils specially built to work the x-ray tubes referred to by Dr. Morton are being made in this country too; and that as long ago as 1914 we mentioned, on page 243 of our catalogue, that prominent gynaecologists have found that "a weak dose irritates and accelerates the growth of malignant cells, and only a strong dose will kill them."—I am, etc.,

London, W., Feb. 16th.

W. E. SCHALL, B.Sc.

THE POSITION OF THE ARMS IN BREECH WITH EXTENDED LEGS.

Sir,—Some of your readers may recall a recent trial in which a medical man was unsuccessfully sued for negligence because, in a case of breech with extended legs which he attended, the child was born dead.

The doctor in his deposition attributed much of the difficulty of the delivery to the fact that, in addition to the legs, the arms also were extended, and stated that in introducing his hand into the uterus to bring down the legs he found the arms already above the head, though the shoulders were high above the pelvic brim. The prosecution tried to prove that the extension of the arms was brought about by improper pulling on the trunk of the child; but the doctor stoutly stuck to his guns, although the expert witnesses called on his side—of whom I was one—were unable to support his assertion from any similar experience or knowledge of their own.

As a fact, in cases of extended legs the hand is not as a rule introduced much above the knee, and consequently there is no opportunity of ascertaining the position of the arms.

On two occasions lately when dealing with extended legs I have had to introduce my hand up to the head of the child, and in both cases the arms were by the side of or above the head. Moreover, I satisfied myself by test upon a newborn child that when the legs are in full extension the feet and calves take up so much room as necessarily to prevent the arms assuming their normal position on the chest. The practitioner may therefore take it that in every case of extended legs the arms also are abnormally placed, and as a matter of routine should be manually brought down before any attempt is made to deliver the head.

The position of the arms in "impacted breech" is not referred to, as far as I know, in any textbook, though it is obviously important from the obstetric point of view, and on occasions, as in the case I have referred to, it may acquire a medico-legal interest as well.—I am, etc.,

London, W., Feb. 16th,

VICTOR BONNEY.

VACCINE THERAPY IN REGARD TO GENERAL PRACTICE.

Sir,—May I elaborate a point in Dr. Fleming's valuable lecture published in your issue of February 19th? The discovery that pneumococci can be classified into strains by paying attention to their agglutination by serums was made independently but almost simultaneously by the American workers Drs. Dochez and Gillespie, and by Dr. (now Sir Frederick) Lister in South Africa. Lister had the great advantage of working under Sir Almroth Wright during the latter's visit to South Africa, and became adept in his methods of laboratory work. When Sir Almroth returned to England, Lister isolated pneumococci from cases of pneumonia, and found that at a certain stage the serum of a patient strongly agglutinated, and opsonized his particular pneumococcus, but not necessarily the pneumococcus derived from another patient. This furnished him with a clue.

Lister's work, which has proved of enormous economic importance to South Africa, can be studied in his papers

published by the South African Institute for Medical Research, which are to be seen in the library of the Royal Society of Medicine.—I am, etc.,

London, W., Feb. 19th.

A. R. FRIEL.

HEART-BLOCK IN DIPHTHERIA.

SIR,—I am much interested in the case of diphtheria developing heart-block reported by Dr. Clayton Allen in your issue of February 19th. The patient evidently suffered from the condition which has been described previously as "paroxysmal cardiac failure" or "ragal attacks." Although complete heart-block is unusual, yet a few cases are reported in the literature.¹ Three cases of this type are reported in my monograph, *The Circulatory Failure of Diphtheria*, and the mechanism of their production is discussed.²

During the course of some experimental work to show the effect of diphtheria toxin on cats, I on one occasion actually saw heart-block develop. The animal was dying from the effects of diphtherial intoxication when the observation was made. The concentration of its blood had risen to such an extent as to indicate the loss of about half its plasma volume. The animal was anaesthetized and the heart exposed. The muscle of both the auricles and the ventricles was seen to be in a state of fibrillation. Saline was run into the saphenous vein so as to reduce the concentration of the blood and to increase the volume in circulation. The fibrillation ceased and the heart began to beat. At first the ventricle responded to every fourth, then to every third, later to every second, and finally to every beat of the auricle. That is, there occurred progressively a 4:1, 3:1, and 2:1 heart-block. I therefore suggest that heart-block in diphtheria is not due to a specific effect of the diphtherial poison on the neuro-muscular tissue of the auriculo-ventricular bundle, nor yet to an alteration in the conducting power of the myocardial tissue as a whole from the direct action of the toxin, but is rather an effect of the lowered and hampered metabolism characteristic of the disease, which in its turn is dependent on leakage of fluid from the blood vessels, with a resulting concentration of the blood and reduction in its volume.

With regard to prognosis, it may safely be said that patients who develop attacks of paroxysmal cardiac failure of this type, treated by the methods at present available, almost invariably die. The treatment of very severe cases of diphtheria with large doses of serum will, presumably, prevent the occurrence of this most fatal complication in a proportion of instances. At Plaistow Hospital cases of the severity described in Dr. Clayton Allen's communication are given doses of from 30,000 to 90,000 units of antitoxin. Most authorities are agreed that it is inadvisable to use hot fomentations to the swollen neck, as they tend to increase the absorption of toxin. When an attack of paroxysmal cardiac failure occurs or is impending atropine hypodermically gives most relief, probably from its effect on the vagal terminals in the heart. It should, I think, be given regularly, say every four hours, to all diphtheria patients with a slow pulse (under 50) who are very ill. The foot of the bed should be raised so as to ensure the best possible circulation to the vital nerve centres. The best stimulant to use during the attacks is ether given intramuscularly. Personally, I avoid strychnine, as I think it does more harm than good.—I am, etc.,

M. ESTHER HARDING, M.D., M.R.C.P.,

Late Medical Officer, Plaistow Fever Hospital.

London, Feb. 19th.

RISKS AFTER OPERATION ON TONSILS AND ADENOIDS IN OUTDOOR CLINICS.

SIR,—I am surprised to hear that the operation for tonsils and adenoids is still done, as the writers in the present correspondence suggest, in outdoor clinics. In Bradford this has not been done to my knowledge—certainly not by myself, and, as far as I know, by any of my colleagues—for years. When I read the remarks of such authorities as Sir William Milligan, Mr. Herbert Tilley, and Dr. P. Watson-Williams I am surprised that in their respective cities more advanced arrangements have

not been made to have the operation as safe as possible and reduce the complications to a minimum. I presume that these gentlemen have the misfortune to have boards of management who pay no attention to the recommendations of their medical staffs, and are therefore not fit for the position of trust in which the subscribers to the hospitals have placed them. What is necessary for the wealthy private patient is necessary for the hospital patient.

I have been busily engaged in this type of work for close on thirty years now, and during that period have done the operation a few thousand times. Sir William Milligan says that "deaths from the anaesthetic are still too frequent, and acute otitis media, mastoiditis, glandular infection, haemorrhage, etc., are practically unknown if the child is kept in bed for two or three days." As it has been the custom here never or hardly ever to send patients home the same day as the operation, but to keep them in at least one day, I am in a position to agree that complications are rare under such conditions. I have only once seen a death from chloroform; I have never had a death from haemorrhage, though I have had several reactionary haemorrhages, which never gave further trouble than pallor for a day or two at the worst; I have had one very bad case of mastoiditis, which went on to lateral sinus thrombosis, meningitis, and death. In the last case—a private case—the patient had two days' preliminary treatment in a nursing home and was kept two days in the home afterwards, and when he was discharged all seemed well with him, but the day afterwards acute otitis media set in, with the calamitous result recorded. Apart from the death under the anaesthetic (chloroform), my worst cases have been private cases carefully attended to in good nursing homes.

I was asked many years ago to establish a clinic with sixteen beds for operative work of the ear, nose and throat, by the Bradford City Council for the school children. In Leicester there is apparently an institution of the same kind. In this little institution I always admitted the patients in the evening and operated on them at 9 o'clock in the morning. They were kept in the hospital till I came the following morning, and discharged them if fit, and if I was not satisfied with the case they were kept in longer. They had every care which any private patient could command. The results were very good. The operation done was the enucleation of the tonsils in their capsules in practically every case. In the Royal Eye and Ear Hospital I operated on the day of admission, but the patients were kept in the hospital the following night, and the results were also as good as I could expect. At the Royal Infirmary the same procedure is followed.

I cannot imagine distinguished surgeons permitting boards of management to allow such an arrangement to continue as the necessity of operating on tonsils and adenoids in an outdoor clinic, and permitting a host of crying children to be taken to a recovery room and remain there vomiting a short time, and then, when they have apparently recovered, allowing them to be taken home. I have no doubt that the complaint will be made "short of money"; then I say that any board of management which is so useless as not to be able to raise the necessary money to have such a necessary clinic founded ought to be replaced by one which can warrant the necessary trust. I am sure that if the subscribers knew the full facts plenty of money would be forthcoming.

As long as such operations as the removal of enlarged tonsils and adenoids are done in out-patient departments without the necessary indoor treatment, and as long as gentlemen accept the honour of being placed on the committees of the voluntary hospitals and take little trouble fully to discharge their duties as such, so long will the incomes of our voluntary hospitals show adverse balance sheets, and so long will socialists and others clamour for the taking over of our voluntary hospitals by the State.—I am, etc.,

Bradford, Feb. 8th.

ANDREW LITTLE.

SIR,—I have not noticed in this correspondence any mention of the fact that institutions have already been provided for the purpose of admitting children for operation and for their detention for two days subsequently.

Over 1,000 cases have thus been dealt with at the "Cyril Henry Treatment Centre" under the L.C.C.

¹ Rohmer, *Jahrb. f. Kinderheilk.*, 1913; Parkinson, *Heart*, May, 1915; Hume and Clegg, *Quart. Journ. Med.*, October, 1914; Price, *Diseases of Heart*, 1918, p. 122.

² Harding, *Circulatory Failure of Diphtheria*, Heart-block, pp. 89-91; Cases, pp. 91, 98, 99.

scheme for treatment of school children, and I think all connected with the centre are agreed that this is a much better plan in every way than the older method of sending the child home almost immediately after the operation.

There may be other similar institutions throughout the country, but probably London gave the lead in this matter.—I am, etc.,

London, S.E., Feb. 8th.

E. J. MORTON.

TREATMENT OF THE PRE-OPERATIVE STAGE OF ENLARGED PROSTATE.

SIR,—I am glad Mr. Thomson Walker agrees that there are some cases which do not require operation, and I regret I misunderstood him. However, I fancy I could bring to his notice, in another publication, this advice which he now repudiates.

I do not wish to defend the catheter, but I must say I think it is often a maligned good. True, sepsis usually follows its use, but if a little common sense were used in addition to strict cleanliness, the evils would be much fewer—at least that is my experience. If, to wit, the anterior urethra were first washed out, sterile liquid paraffin injected as a lubricant, and if after withdrawing the urine (a rubber catheter, with or without a coude whalebone stylet, is best) a mild antiseptic were allowed to flow into and out of the bladder, how few would be the organisms left in the bladder after this small additional trouble! The paraffin, as it were, imprisons them, and prevents trauma, if used in this way.

But if sepsis should follow, what then? Operate; and operation in the presence of much residual urine with sepsis often is safer than without it—the patient is auto-inoculated; not that I am defending sepsis. Take now the bugbear cancer; this usually is cancer *ab origine*, and although it often follows enlarged prostate, is this cause and effect?

I never thought there was only one cause for frequency of micturition, or that Mr. Walker advised operation for it; if so, the half of all persons over 50 would require operation. Renal diseases and scores of other things cause this symptom (for instance, "mountain dew").

Mr. Neve's remarks are interesting. Massage only relieves congestion, but that is a great deal; moreover, prostatitis often accompanies "enlarged prostate." Age is no bar to inflammation, and I have often seen mistakes made. Orchitic extracts are not likely to do very much good—indeed, orchidectomy was the "cure" some years ago. Gout and rheumatism, I am sure, are big factors in prostatic changes, and I should like to add that I have found "senile prostate" (a better name) common in the priesthood, amongst whom the orthodox supposable causes (infective) are not thought to be very prevalent.—I am, etc.,

JAMES MACMUNN.

London, E.C., Feb. 8th.

THE FALL IN THE TUBERCULOSIS DEATH RATE.

SIR,—The announcement of the Registrar-General that the death rate from tuberculosis fell in 1919 to a lower point than it had ever before reached has given rise to surprise and some curious comments from those who had not expected, and perhaps had not worked to attain, this satisfactory result. The writer, with countless other workers in the field of preventive medicine, has been confidently expecting this fall, and does not, like the medical correspondent of the *Times*, find it unaccountable. In a letter which you published nearly twelve months ago I maintained that the rise in the tuberculosis death rate which occurred before and during the war was due to temporary factors, including influenza, and was not the result of paternal legislation, which if it had diminished real wages, had also decreased destitution. I also ventured to prophesy that we should very soon see the deaths from tuberculosis reach a lower figure than ever. My forecast has been fulfilled earlier than I expected, and must be a cause of great satisfaction and congratulation to all those who have for many years been labouring to diminish the ravages of consumption.

General hygienic measures and a higher standard of living among the poorer classes have increased their resistance to the tubercle bacilli; notification of tuberculosis and tuberculosis dispensaries have ensured earlier

treatment of commencing cases, and sanatorium treatment and the educational steps taken by medical officers of health have taught the practice of living and sleeping in the open air and the avoidance of infection. If to these factors we add diminished alcoholism and improved work-shop hygiene we hardly need look farther for the cause of the fall in tuberculosis mortality.

As one who has had to retire from the line of battle, I can only wish God-speed to those who are still in it. May their efforts continue to produce equally satisfactory results.—I am, etc.,

Montreux, Feb. 16th.

SIDNEY DAVIES,
Late M.O.H. Woolwich.

EYE-STRAIN IN CINEMATOGRAPH HALLS.

SIR,—In your issue of February 19th you state that the committee appointed by the Illuminating Engineering Society believes that cinematograph ocular discomfort arises mainly from the abnormal angle at which the eyes of spectators are directed upwards to the pictures.

In a paper published in the *British Journal of Ophthalmology* for November, 1920, I gave some personal experience gathered in a large war hospital, where we had cinematograph exhibitions from three to six times a week. The ocular discomfort I experienced was so great that often I had to leave the hall. I usually sat 45 ft. away from the screen, and so the angle of elevation in my case was small and had nothing to do with the production of the discomfort. For nearly four years I had the subject occasionally under consideration, and came to the conclusion that the locality of the discomfort is in the retina and that it is caused by central or uneven illumination of the retina while the eye is in a condition of dark adaptation. If the light on the screen is very bright or bright in patches the peculiarity is exaggerated and the discomfort increased.—I am, etc.,

Glasgow, Feb. 19th.

J. ALEXANDER WILSON.

THE COLLECTIVE OPINION OF THE PROFESSION.

SIR,—As a non-member of the Association, may I venture to criticize the construction of the body which the British Medical Association proposes as "really representative of all the organized medical profession, both generally and sectionally"? (SUPPLEMENT, February 19th, p. 42.)

If I understand aright, Dr. Addison desired a body so far representative that he would not be worried by deputations from other bodies each capable of expressing opinions adverse to the policy of the British Medical Association and each able to influence a considerable body of opinion. Since I was present when Dr. Addison expressed his desires, there is some warrant for supposing that I am correct in so understanding him. There are two bodies to which no reference is made by the British Medical Association, each of which has a considerable number of members and each of which is in a position to influence opinion outside its own ranks by its journal or by pamphlets, etc. In other words, these two bodies have sufficient funds and sufficient membership to be quite definite factors in medical opinion. I refer to the Medico-Political Union and the National Medical Union.

These bodies are not mentioned in the British Medical Association Memorandum, and, since their existence is well known, one can only conclude that the omission is deliberate. It might almost be construed as a slight. There is also the Federation of Medical and Allied Societies, and this body is claiming that Dr. Addison will recognize no body which does not include representatives of the federation. This claim is made quite explicitly, and surely merits the attention of the British Medical Association, however much or little it may itself approve of the federation's constitution.

With these three bodies neither mentioned nor invited to assist the British Medical Association, it should be patent to all that we have made no greater approach to professional unity than obtained before. Why, then, was the Memorandum issued? As a non-member I am very sure that neither my medico-political associates nor myself have any representation therein. Not being children, we shall see to it that Dr. Addison is informed that we were not even invited to agree. We shall then have arrived in the *status quo ante*, after wasting some months in getting there.

Is there no statesman in the British Medical Association big enough to rise above the chance of slighting his opponents? I venture to think that the profession requires a statesman now more than ever, a man at least big enough to put the general welfare before the opportunity of a ponderous snub. May we know the names of the statesmen who produced this Memorandum in the name of your Association?—I am, etc.,

Severcauks, Feb. 19th.

GORDON WARD.

The Memorandum in question was discussed and approved by the Council of the British Medical Association at its meeting on February 16th.

THE NAVAL MEDICAL SERVICE.

SIR.—The question of reform in the Naval Medical Service has been discussed freely by officers who held temporary commissions during the war. I send you a few of the reasons which may be contributory to the comparative failure of the service to augment its numbers from our very considerable numerical strength. The following statements were put down in 1919 after a three years' experience in a leading naval hospital.

There was an absence of a sufficient number of senior men with the capacity for teaching, and this, together with a complete absence of registrars, proved serious to the large body of recently qualified officers, many of whom had not held a house appointment. Registrars have been found to be part and parcel of the efficiency of civilian hospitals. The senior officers of hospital sections were in some cases quite innocent of modern medical knowledge, and often they appeared to be overburdened with paper work. In neither case were they to blame. The war has produced specialists in certain departments, but even as late as 1919 the Medical Department at the Admiralty declared, so I am informed, that the navy had no use for a neurologist in peace time.

The fact that medical officers retained their wards for very brief periods in some cases was due no doubt to the constant changes in personnel, but it resulted in many patients having as many as four and six medical attendants in a week. It was the exception for a patient needing treatment at night to receive it from a doctor who had seen him before.

Many patients, trained men, were invalided with diagnoses little short of grotesque on account of a lack of proper application of medical knowledge, and this professional flippancy was made to take an exaggerated form by reason of the multiplicity of naval medical signatures which the papers carried. The system of policing and patrol as witnessed in hospital gained few advocates from our number.

The conviction was forced upon some of us that in the service a habit can be acquired fairly readily of placing chances of promotion before medical duties which involved diagnostic and prognostic responsibility. This habit appeared to be due chiefly to the obvious difficulties under which the duties of fairly senior officers in particular had to be carried out. A career seemed to be in least danger to the officer who tried to make sure that he did nothing which could be proved wrong; in other words, a premium was placed upon a professional incapacity to face all and every medical problem. Happenings quoted from the working of the mental department have helped to support this conviction. It was common for ratings who were obviously sane on admission to be required to spend one or more days and nights in the asylum because, months before may be, they suffered from a mental disability, however transient. Once a diagnosis of mental disease was given in the service it stayed with the patient from hospital to hospital, diluted, perhaps, *en route* with the statement of the doctor who caused the diagnosis to be perpetuated that he "observed no evidence of mental disease." Similarly with cases of epilepsy and heart disease, so called.

A boy, aged 16½, was successfully invited by a senior officer to spend his first night at any rate in the asylum. The officer of the department did not see the lad until the next day, and he then found that the patient had been completely cured for three months past of a temporary mental confusion following "influenza" at Simonstown, and that he had enjoyed complete liberty during this period. Immediate transference to a medical ward was insisted upon, in spite of the statement that there was no vacancy. Nevertheless, the boy was required, in order to obtain his dinner, to return to the asylum for the second time on this day.

There was but one ward for cases under observation and for those already certified insane. Several sane patients who were unable by reason of disease to express their thoughts in coherent speech, aphasics, were passed into the asylum on admission, in accordance with the principles of panic. Yet the navy has no place for a neurologist in peace time!

Another memory is that of all newly admitted ratings who brought with them a report that their blood serum gave a positive Wassermann reaction being swept into the venereal wards. For many months the tabetics and the owners of chancres, the hemiplegics, and the victims of urethral "strain" were apt to occupy adjacent beds, but this arrangement appeared to be due to the enthusiasm of a commissioned ward master rather than to the wishes of any medical officer.

Much good work was done by overworked and conscientious officers in the face of considerable difficulty, and certainly the writer will never forget the exceptional kindness which all temporary officers received at the hands of the permanent service, but in hospital, at any rate, there was something wrong with the machinery of medicine, and it is the recollection of it which prevents some of us from recommending wholeheartedly to medical students the Naval Medical Service. All of us would be proud of an opportunity to help this branch to be a completely worthy member of the finest service in the world, and it is on this account that this letter is written. I enclose my card.—I am, etc.,

Harley Street, W., Feb. 19th.

"M.D."

MILITARY MEDICAL HISTORY.

SIR.—I was extremely interested in Major-General Eratt's letter suggesting the appointment of a professor of military medical history. The study of the medical side of past wars is both fascinating and instructive. Personally, I have always been interested in military history, and in reading over the memoirs and biographies of officers and men it has often struck me what a wealth of material relating to military medicine is hidden away among the leaves of these books. This material unearthed and sifted would surely prove instructive and of value to all officers of the R.A.M.C. What vivid glimpses of army medical administration in past wars we get in some of these memoirs! To read of the veritable charnel houses, misnamed hospitals, in Napoleon's Russian campaign, and of the state of some of our base hospitals, such as Belem and Celorico in the Peninsula, makes one realize what vast strides have been made in the Army Medical Services. In those days, and even down to the "fifties" and later, for a man to be sent to hospital was practically to be sentenced to death. What a change to our magnificently equipped hospitals in France and Flanders in the great war!

Yet the individual regimental surgeon is always spoken of with admiration. It is the Administrative Department which is nearly always at fault. The regimental surgeon carries on in the face of tremendous difficulties and dangers. He is always cheery and bright, and sometimes, when all the other officers are struck down, he leaves his wounded for a time and takes command himself. Who is there but can admire the steadfast courage and unselfish devotion of such men as Joseph Fayrer in the Residency at Lucknow, Surgeon Kelly at Cabul in '79, Dr. Philip Frank who tied the carotid under fire at Balan in '70 (a knightly soul who I was privileged to know), and Martin Leake, who won the V.C. with bar!

There are many lessons to be learned from this last great war. Though the medical arrangements in the western theatre of the war were all that could be desired, yet in some of the various "side shows" these arrangements were anything but satisfactory. The lessons of past wars seem to have been forgotten in many instances. The medical history of the great war should prove of great value to the future generation of army medical officers.—I am, etc.,

RUSSELL V. STEELE,

Devizes, Feb. 12th.

Captain 1ste R.A.M.C.

THE PREVENTION OF VENEREAL DISEASE.

SIR.—The letter of Dr. Gifford, of Reading, gives one great pleasure. Here is someone at last who has gone to the root of the sexual evils which abound to-day.

Dr. Gifford has attacked the proper quarter, and that is

the parental upbringing of the young. Every young man and woman ought to be educated at home by the parents in self-respect with regard to bodies as well as brains. Until that is done, and the young understand for what their sexual functions are, the innocent future generations will continue to be tainted when born as is the case to-day.

When we hear of male medical students in the common-room of a London college stating that it is not possible for men to remain without sexual intercourse until marriage, it is about time we had such letters as that of Dr. Gilford brought well to the front.—I am, etc.,

London, E., Feb. 13th.

E. McHARDY, M.B., Ch.B.

Medico-Legal.

OFFENCES UNDER THE MEDICAL ACTS.

In our issue of February 5th we drew attention to a woman calling herself Margaret Crawford (or Margaret de Lancy Williams) whose arrest was sought on a warrant by the police for alleged offences against the Medical Acts, 1858. This woman was arrested in Dublin on February 10th, and brought before Mr. D'Eyncourt at Marylebone Police Court on February 18th to answer four summonses preferred by the Medical Defence Union, Ltd., of falsely pretending to be a general medical practitioner in August and September last, and of falsely using the title of Bachelor of Medicine on three death certificates. The accused pleaded guilty and was fined £20, with five guineas costs, for each of the offences.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

Diploma in Medical Radiology and Electrolgy.

On the recommendation of the Committee on Medical Radiology and Electrolgy the diploma in medical radiology and electrolgy has been granted to J. E. A. Lynham, M.D., A. E. H. Pinch, F.R.C.S., W. J. Turrell, M.D., A. E. Barclay, M.D., and F. Heruaman-Johnson, M.D.

At a congregation held on February 18th the following degrees were conferred:

LL.D. (*honoris causa*).—Dr. A. Calmette (subdirector of the Institut Pasteur), Sir Patrick Manson, G.C.M.G.

M.S.—O. G. Morgan.

M.B., B.Ch. G. A. Harrison.

B.Ch.—Leslie S. Gathergood.

UNIVERSITY OF LONDON.

A MEETING of the Senate was held on February 16th.

The Prince of Wales.—The Vice-Chancellor (Dr. Russell Wells) stated that the Prince of Wales would receive the honorary degrees of Master of Commerce and Doctor of Science on May 5th, and had promised to attend the graduation dinner on that evening. The Guildhall has been placed at the disposal of the University for this purpose by the Lord Mayor and Corporation, and the Lord Mayor has accepted an invitation to be present.

Professor of Obstetrics, London School of Medicine for Women.—Miss Anne Louise McIlroy, O.B.E., M.D., Ch.B., D.Sc.Glasg., was appointed to the university chair of obstetrics and gynaecology tenable at the London School of Medicine for Women. Miss McIlroy was educated at the Universities of Glasgow, London, Berlin, Vienna, and Paris. She has held the appointments of assistant surgeon at the Glasgow Female Lock Hospital, district obstetric physician in charge of the West End Branch of the Glasgow Royal Maternity Hospital, assistant gynaecological surgeon at the Royal Samaritan Hospital, Glasgow, and senior assistant to the Muirhead Professor of Obstetrics and Gynaecology at the University of Glasgow. From 1915 to 1919 she was surgeon in charge of the Girton and Newnham Unit of the Scottish Women's Hospitals for Foreign Service, which was stationed at Salonica and Belgrade. Since 1919 she has been gynaecological specialist in the 82nd General Hospital at Constantinople, in which she acted as surgical specialist during the absence of the senior professor she will be director of the Obstetrical surg and the medicine for Women is attached.

Chair of Embryology.—Professor James Peter Hill, D.Sc.Edin., F.R.S., was appointed to the university chair of embryology tenable at University College. In 1892 he was appointed tenable at University College, and in 1904 lecturer on embryology, demonstrator in biology, and in 1906 he has held the in the University of Sydney; and since 1906 he has held the Jodrell chair of zoology and comparative anatomy at University College.

Graham Scholarship in Pathology.—The Graham Legacy Committee reported that they had appointed Mr. V. R. Khanolkar, M.B., B.Sc., to the Graham scholarship in pathology for two years from April 1st, 1921. The value of the scholarship is £400 a year. Since October last Mr. Khanolkar has been assistant bacteriologist in University College Hospital. He has had considerable experience both as a teacher and as an investigator, and the proposed subject of his research is "Focal activity of the kidneys."

UNIVERSITY OF BRISTOL.

The following candidates have been approved at the examinations indicated:

M.D.—A. R. Heber.

FINAL M.B., Ch.B.—Part II (*Completing Examination*): W. H. Royal, Marjorie Wadsworth (with first-class honours). Part I Only (*Including Forensic Medicine and Toxicology*): W. A. Jackman, P. Phillips. Part I Only: Phyllis Beames, M. Critchley, J. R. Duerden, Winifred G. Nott, J. A. Prichard, W. K. A. Richards, Victoria S. Tryon.

D.P.H.—Part II (*Completing Examination*): T. V. Cant, A. D. Fraser, G. C. Williams.

Obituary.

WILLIAM ODLING, M.B., F.R.S.,

Late Waynflete Professor of Chemistry at Oxford.

PROFESSOR WILLIAM ODLING, who died at his residence in Oxford on February 18th, was 91 years of age, and had been Waynflete professor of chemistry in the University of Oxford for forty years; he succeeded Sir Benjamin Brodie, the first holder of the chair, in 1872, and only resigned in 1912. He was the son of a medical practitioner in Southwark, received his medical education at Guy's Hospital, and graduated M.B.Lond. in 1851. He was elected a Fellow of the Royal College of Physicians of London in 1859, during the presidency of Dr. Thomas Mayo, and was its senior Fellow at the time of his death. He never practised medicine, however, but devoted himself entirely to chemistry, having been appointed director of the chemical laboratory in Guy's Hospital at the age of 21. In 1863 he became lecturer in the subject at St. Bartholomew's Hospital Medical School, and five years afterwards succeeded Edward Frankland as Fullerton professor of chemistry at the Royal Institution. In his early days he wrote a number of papers on theoretical considerations regarding the constitution of organic bodies, and later gave much attention to practical questions, such as the purification of rivers, the analysis of drinking water, and the chemistry of bread-making; he wrote a number of textbooks which were popular in their day, but during the later part of his life he ceased to do much in the way either of research or writing. He married, in 1872, the daughter of Mr. Alfred Smee, F.R.S., and leaves three sons, one of them a lecturer in the University of Leeds.

JAMES HUNTER, F.R.C.S., F.R.C.P. EDIN., F.R.S. EDIN., Liberton, Midlothian.

DR. JAMES HUNTER, who died suddenly in Edinburgh on February 14th, was known to many generations of students both inside and outside the University of Edinburgh as a teacher and an examiner in physiology. He was elected to the Fellowship of the Royal College of Surgeons of Edinburgh forty-three years ago, and soon came to devote himself with zeal to physiology, giving lectures thereon in the Minto House School of Medicine. Later he acted as examiner in that subject and in biology for the Triple Qualification of the Royal Colleges of Edinburgh and Glasgow. He was in no sense a one-subject man, for his enthusiasm extended outside of medicine and invaded astronomy and geology and theology, a fact which sometimes made a curious appearance in his oral examining in physiology and biology. He was a devotee of science in many of her departments, and at one time took a great interest in the work of the Royal Society of Edinburgh. Although retired from active teaching some years ago Dr. Hunter courageously returned to it for a short period during the war when Edinburgh was sorely depleted of her extramural staff. He moved quietly about amongst his fellows, seeking no honours, but always doing his daily work in an effective and unostentatious fashion, and his death will leave a blank in the circle who knew and loved him well.

MR. ALEXANDER DUNCAN, B.A., LL.D., secretary and librarian of the Royal Faculty of Physicians and Surgeons, Glasgow, died on February 14th. He had held the appointment for over fifty-five years, and had a most extensive and profound knowledge of medical literature. He was born at Muckhart, near Dollar, graduated B.A.Lond., and for a time was a schoolmaster in Kirkintilloch. In 1865 he was appointed secretary and treasurer to the Faculty of Physicians and Surgeons in Glasgow. By compiling and publishing catalogues of the library he facilitated greatly the work of medical research.

and he prepared a history of the medical profession in the West of Scotland, entitled *Memorials of the Faculty of Physicians and Surgeons of Glasgow, with a Sketch of the Rise and Progress of the Glasgow Medical School and of the Medical Profession in the West of Scotland*. He received the honorary degree of LL.D. from Glasgow University in 1898.

Medical News.

ON February 21st the Council Club of the Royal Society of Medicine entertained Sir Dawson Williams, Sir Charles Ryall, and Sir Maurice Craig at dinner. The President of the Society, Sir John Bland Sutton, was in the chair, and among those present were Sir R. Hill, K.C.V.G., Medical Director General R.N., Sir John Goodwin, K.C.B., D.G.A.M.S., Sir Arbuthnot Lane, Bt., Sir J. Dundas Grant, Dr. R. A. Gibbons, and Mrs. Schanheeb, M.D.

A CONFERENCE on industrial welfare, arranged by the society bearing that name, will be held at the Mansion House on March 2nd. The Lord Mayor will preside and among the speakers will be the Duke of York, the Home Secretary, the President of the Board of Education, and the Right. Hon. J. R. Clunes, M.P.

AT a meeting of the Radnorshire Panel Committee held at Llandrindod Wells on February 18th, Dr. Harding of New Radnor (Chairman of the Radnorshire Panel Committee and Chairman of the Radnorshire Insurance Committee) was presented with a silver silver inscribed as follows: "Presented to Dr. R. Harding on his marriage, December 1st, 1920, by the panel practitioners of Radnorshire, as a small token of their appreciation of his services in connexion with national health insurance." The presentation was made by Dr. T. Murray of Llandrindod Wells, who in the course of his remarks made reference to the untiring energy and determination with which Dr. Harding had fought in the interests of rural practitioners, especially in regard to extra mileage.

DR. GUSTAV MONOD WALTER of Vichy is at present in London to discuss with the profession here the possibility of establishing some practical organization for encouraging closer co-operation between the profession in the two countries. Some time ago independent members of the profession in France formed a propaganda section, it has now been enlarged by the addition of representatives of the teachers of the medical schools in France, and is known as the Association pour le Développement des Relations Médicales (A.D.R.M.). This body, which works under the auspices of the Faculté de Médecine, is prepared to offer the advantages of its organization to British medical practitioners visiting Paris in return for similar advantages to be placed at the disposal of French doctors coming to this country. The suggestion is under the consideration of the Fellowship of Medicine.

THE foundation stone of a new home for the nurses of St. Bartholomew's Hospital was laid by the Queen on February 17th. The nursing staff has hitherto been housed in a number of old buildings on the site of which the new building is to be put up, the first of the four blocks which have been planned is now building, and the others will be erected as funds permit. The blocks will be connected on each floor by enclosed bridges, and each floor of each block is to be self contained and capable of being isolated entirely in such an event as fire or infection. Separate bedroom accommodation will be provided for the whole of the nursing and female domestic staff, offices for the matron and her assistants, various common rooms and dining halls, sick bay wards for twenty-five nurses, a lecture theatre, a library, and an examination room. The Queen was received by the Prince of Wales, president of the hospital, who presented to Her Majesty the hospital treasurer and almoners and representatives of the medical and nursing staffs. Prayer was offered by the Bishop of London, and the Prince then read an address which stated that the governors had long recognized the need of improved accommodation for the nursing staff, and were grateful that, thanks to public munificence, they were now in a position to erect the first block of a new home which would ensure healthy conditions of housing, comfort, convenience, and economy of administration. The Queen then handled the trowel and mallet, and the stone was well and truly laid. The Prince of Wales, in expressing the thanks of the governors, mentioned that "Bar's" had lately received some munificent donations—one of the individual donations was of £25,000, and another of £10,000.

DR. ARCHIBALD LEITCH has been appointed Director of the Cancer Hospital Research Institute.

A THIRD course of lectures and practical courses of instruction for a diploma of psychological medicine will be given this year at the Maudsley Hospital. The first part, by Sir Frederick Mott, F.R.S., Dr. Gollin, and Dr. Devine, will begin in the first week of April, the second will be held in October. Further particulars can be obtained from the Fellowship of Medicine, 1, Wimpole Street, W.1, which will issue tickets. The fee for the full course is 15 guineas; for each part separately, 10 guineas.

POST GRADUATE courses in dermatology and venereal diseases will be given this spring at the Hôpital Saint-Louis, Paris, under the direction of Professor Jeanselme. The course in dermatology will begin on April 8th and conclude on May 28th, it will include lectures and clinical demonstrations, including a special course on ringworm by Drs. Sabouraud and Nouré. The course in venereal diseases will begin on May 30th and end on July 7th. The fee for each course is 150 francs. All further particulars can be obtained from M. Marcel Bloch, Chef de Laboratoire à la Faculté, 40, rue Bichat (10^e), Hôpital Saint-Louis.

A COURSE of four public lectures on the history of plant delineation, a subject of importance in the history of medicine, will be given during March in the Botany Department of University College, London. The first two, on the art of the ancient empires and the dark and middle ages, will be delivered by Dr. Charles Singer, and the other two, bringing the subject down to recent times, by Dr. Agnes Arber. The lectures are given on Wednesdays at 5 p.m., beginning on March 2nd, and are open to the public without fee.

A COURSE of twelve lecture demonstrations on gonorrhoea for senior students of the hospital and medical practitioners will be given at the London Hospital, beginning on March 1st, at 4.30 p.m., by the chief assistants to the Genito-Urinary Department. Mr. Clarkson's demonstrations on the male will be given on Tuesdays and Thursdays, and Dr. Simpson's on women on Wednesdays and Fridays. Particulars can be obtained from the Dean.

DR. A. E. BARCLAY, medical officer of the X-Ray and Electrical Department, Manchester Royal Infirmary, informs us that a series of seven plaster models made from x-ray observations and showing the normal stomach and the effect of posture upon its shape have been placed on exhibition at the Royal College of Surgeons.

THE 1921 report of the Officers' Families Fund covers a period of nearly two years, and shows that the administration of this important fund, which relieves many hundreds of necessitous cases, is being well and economically carried out, the work has naturally diminished somewhat during the last two years, and the institution of the Officers' Association, with which the Fund has a working arrangement, has also relieved it in some measure.

OF the twenty-one successful candidates at the recent examination of the Sanitary Inspectors' Examination Board ten received instruction at the Battersea Polytechnic, six at the National Health Society, three at the Royal Sanitary Institute, and one from the Hackney Institute, the remaining candidate was in office.

ON the recommendation of the Minister of Health, the King has been pleased to appoint Mrs. Ellen Frances Pimmet to be a Commissioner of the Board of Control, to fill the vacancy caused by the retirement of Mrs. Mary Dendy.

THE Nurses Registration Act, 1919, empowered the General Nursing Council for England and Wales to make rules with respect, among other matters, to the uniform or badge which may be worn by nurses registered under the Act. Neither uniform nor badge are compulsory, but the Act provides that any unauthorized person using the uniform or badge shall be liable on summary conviction to a fine not exceeding £10 for the first offence, and £50 for any subsequent offence. The General Nursing Council has now issued a notice inviting expressions of opinion from members of the nursing profession as to the design of our door and indoor uniforms, and especially as to whether the usual cloak and bonnet for outdoor wear will be preferred, or a coat and hat. Communications should be addressed to the Registrar, General Nursing Council for England and Wales, Room 104, third floor, Ministry of Health, Whitehall, S.W.1.

IT is announced that the University of Edinburgh *Roll of Honour, 1914-1919*, edited by Major J. E. Mackenzie, with 843 portraits, is in the press, and will shortly be published by Messrs. Oliver and Boyd.

THE Lord President of the Council has appointed an Interdepartmental Committee on Patents to consider the methods of dealing with inventions made by workers aided or maintained from public funds, whether such workers be engaged as research workers or in some other technical capacity. The Committee is to outline a scheme to give a fair reward to the inventor, and thus encourage further effort while protecting the national interest. Among the members of the Committee are Dr. H. H. Dale, F.R.S., head of the Department of Biochemistry and Pharmacology of the Medical Research Council. Communications with regard to the work of the Committee should be addressed to Mr. A. Abbott, 16 and 18, Old Queen Street, Westminster, S.W.1.

WHAT is stated to be the largest collection of British manufactures ever gathered together, has been opened for a fortnight at the White City, London, in the shape of the British Industries Fair, arranged by the Department of Overseas Trade. Similar fairs have been opened in Birmingham and Glasgow. The fair brings within the space of forty acres or so a comprehensive exhibit of British industry and invention. The two sections which are most likely to interest any medical visitor are those devoted to chemical preparations and scientific instruments. In each of these a little market town of some thirty separate displays has been assembled. The exhibition of chemical preparations is of a very miscellaneous character, although it has some attractive features, but the other section will be the greater surprise to those who are aware how dependent we have been in the past upon foreign enterprise. It is difficult to think of anything in the way of scientific instruments and laboratory equipment which is not represented by British-made articles, and the exhibit of optical glass and of glassware generally is as good an illustration as anyone could desire of British genius and craftsmanship.

THE issue of *Nature* for February 17th was a special number containing a series of articles on the principle of relativity, by Einstein, Lorentz, Sir Oliver Lodge, and others, including one by E. Cunningham tracing the long history of the idea.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Ailology*, Westrand, London.
2. FINANCIAL MANAGER (Advertisements, etc.), 429, Strand, London.
3. MEDICAL SECRETARY, *Medisecra*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus*, Dublin; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, Edinburgh; telephone, 4361, Central).

QUERIES AND ANSWERS.

"M.B." asks for suggestions regarding the treatment of a patient, aged 60, who suffers from intense itching on both legs, below the knee, when warm in bed. The patient has a good appetite, no varicose veins, no sugar in the urine, and has a very slight patch of eczema—so slight as to be hardly noticeable—on one leg.

INCOME TAX.

"MEDOC," who has changed his address, asks (1) whether he should apply for a declaration form or wait until the authorities supply one on their own initiative; (2) can he deduct the cost of travelling from his residence to his consulting room? (3) how does the three years' average apply?

"Medoc" has presumably commenced an entirely new consulting practice. Legally he is under an obligation to render a statement of his liability whether it is specifically applied for or not; it is also preferable to make matter for two or three years and then having to make good arrears of income tax. The cost of travelling would not be admissible unless the practice is carried on at the residence as well as at the consulting rooms. The army emoluments cannot be averaged with professional profits, and the liability will be determined for the first year on the

earnings of that year, for the second year on the same amount, for the third year on the average of the first two years, and thereafter on the average of the three previous years' earnings. This is, of course, subject to any change in the law as to the average, and to the fact that as the law stands there is a proviso that during the first four years the "average" assessment can in each year be reduced to the amount of that year's profits.

LETTERS, NOTES, ETC.

CURE OF HAEMORRHOIDS WITHOUT OPERATION.

DR. A. WITHERS GREEN writes: All the suggestions made in the article at p. 265 of the JOURNAL of February 19th were dictated to me by my own common sense "years and years ago." I always use zinc oxide or zinc oxide with starch powder, with no atom of that common criminal boric acid. Ladies like a white powder better than a pink calamine. They also like calomel ointment in mild cases instead of that dirty ung. gallae c. opio. I would add: Grease the faeces internally by taking olive oil or liquid paraffin by the mouth; grease the anus before going to stool; use no paper, sponge with cold water, and assume the horizontal position at once with a large cushion under the buttocks, with shoulders not raised, but on the flat.

LUMBAR PUNCTURE IN ACUTE DISEASE.

MR. H. V. DREW, F.R.C.S. (Broadstairs), in the course of a letter, writes: I have in previous communications shown that disease manifestations are primarily due to the influence of toxins on the central nerve centres controlling all the vital processes, and I believe that reducing intraspinal pressure, and therefore absorption of toxins in acute diseases accompanied by grave symptoms, will save many lives and produce a revolution in medical practice. During the influenza-pneumonia epidemics of 1918 I appealed to the Army Medical Service to test my proposal, but it was not done. It follows from my formula above that we have an opportunity afforded for (1) analysing the toxins of disease as manifested in the cerebro-spinal fluid; (2) a simple method of reducing pressure injurious to the higher vital control centres, which in its turn increases absorption of the injurious toxins, causing headache, delirium, and all the other nervous symptoms common to acute diseases, which can only be explained by their influence on the central nervous system; and (3) a means of treating directly, not only symptoms, but diseases at the source, by relieving intraspinal pressure, and by direct injection of suitable remedies, medicinal or antitoxin. Since I first enunciated these views I know of such diverse cases as puerperal eclampsia, pneumonia, and status epilepticus, which recovered under the method suggested. I can recall many fatal cases of pneumonia and other acute diseases in which acute nervous symptoms were present, and to which no relief could be given; a simple tapping of the theca would have brought about immediate relief and ultimate recovery.

In regard to this subject attention may be drawn to paragraph 104 of the Epitome (January 22nd, 1921).

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 38, 39, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 36 and 37.

THE appointment of a medical referee under the Workmen's Compensation Act, 1906, for the Sheriffdom of the Lothians and Peebles is vacant. Applications to the Private Secretary, Scottish Office, Whitehall, S.W.1, by March 16th.

THE following vacant appointments of certifying factory surgeons are announced: Westbury (Salop), Allendale (Northumberland), Colne (Lancaster), Eccles (Lancaster), Hammersmith and Paddington (London), Kirkby Lonsdale (Westmorland), Shap (Westmorland).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Order must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, not later than the first post on Tuesday morning; and, if not paid for at the time, should be accompanied by reference.

NOTE.—It is against the rules of the Post Office to receive post-restant letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

258 Tuberculosis and Heredity.

LUNDBERG (*Scenska Faltarsallstapels Handlingar*, September 30th, 1920) enumerates several arguments in support of the theory that racial homogeneity is a powerful factor, preventing degenerative phenomena, including a predisposition to tuberculosis. The pure bred Jew and gipsy are comparatively immune to tuberculosis even when living in poverty and under other unfavourable conditions, but as soon as they intermarry with other races this immunity quickly disappears. In the north of Sweden, where Swedes, Lapps, and Lapps have intermarried, the tuberculosis mortality is high, whereas in the south, with its pure bred Swedish population, the incidence of tuberculosis is much less. Again, in Iceland the low incidence of tuberculosis may be correlated with the racial isolation of its inhabitants. The same argument applies to the south of Italy, Sardinia, and Sicily, where the incidence of tuberculosis is low in spite of defective hygiene. On the other hand, countries such as Poland and Austria, with racially mixed populations, suffer greatly from tuberculosis. The author produces many other arguments in support of his views, and he suggests that measures directed against tuberculosis simply as a disease of infection and of other extraneous circumstances can be only partially successful, only when tuberculosis is treated also as a disease determined by race biology and heredity can its control be achieved.

259 Protein Therapy in Pneumonia.

MONGLIZZI (*Il Polichinco*, Sez. I, October 4th, 1920) gives an account of protein therapy in 22 cases of pneumonia or bronchopneumonia, which he divides into four groups. In the first group, consisting of 11 patients, a single intramuscular injection of 10 c. cm. of sterilized milk was given. The result was good in each case, and in two surprisingly so, as the pneumonic process subsided within thirty-six hours after the injection. In the second group, which consisted of 7 patients, three injections of milk were given, with an interval of a day between the first and second injections and an interval of forty-eight hours between the second and third. Recovery was rapid after the third injection. In the third group, which consisted of 3 cases, the injection of milk was not followed by any objective or subjective improvement. An intramuscular injection of 200 million of a stock gonococcus vaccine was then given, and was followed by a slight rigor and sharp rise of temperature. The injection was repeated next day with a similar result, recovery henceforward was rapid. The fourth group was represented by a single fatal case, in which an injection of milk, followed by stock gonococcus vaccine, had no effect.

260 Bronchiectasis after Influenza

PARODI (*Il Morgagni*, June 30th, 1920) points out that acute bronchiectasis, as distinguished from the chronic forms, is not infrequent after measles, influenza, and whooping cough—in this order of frequency. Although bronchiectasis follows changes in the bronchial parietes, not every lesion of the bronchi is followed by bronchiectasis, but only certain types. As the result of a study of several cases and pathological reports, the author concludes that in acute bronchiectasis there is always in the very earliest stages a functional alteration of the bronchial walls, followed by severe bronchitis (generally purulent), causing infiltration of the parietes, peribronchial structures and alveoli, and finally leading to bronchiectasis. Full details are given of two cases. As regards treatment, in almost every case the author advises artificial pneumothorax, where the walls of the bronchi are rigid and sclerotic pneumothorax is dangerous and thoracoplasty operation is more suitable.

261 Vaccine Therapy in Typhoid.

BORZOLO and FANZIO (*Il Morgagni*, August 31st, 1920) have treated 57 cases of typhoid with a choleraic vaccine prepared by Loeffler. The usual reaction after an intravenous injection followed—shivering, rise of temperature, sweating, etc. The results on the whole were good, in some cases only one injection was necessary—a critical lowering

of temperature took place in 25 per cent of the cases, and in 30 per cent a decided diminution in temperature and improvement in the general state followed. On the other hand, 33 per cent proved refractory to this treatment. The best time to use vaccine therapy is said to be between the tenth and fifteenth day of the disease. In some cases it may excite hæmorrhage, it is contraindicated in advanced age, in cardiovascular insufficiency, and where severe bronchopneumonic complications exist. There were three deaths in the 57 cases, one died immediately after injection, but in this case, at the autopsy, persistent thrombus and congenital stenosis of the aorta were found to exist.

262, Familial Contagion in Lethargic Encephalitis.

DE LAROCHE (*Paris med.*, September 25th, 1920) states that it is exceptional for the contagious character of lethargic encephalitis to be demonstrated. Out of 114 cases Netter observed only one family in which there were two cases, and even then the first case had not been recognized. At Sarrebuch two sisters were attacked, but they were living in an epidemic environment. Laroché reports the case of a gendarme who developed lethargic encephalitis on April 20th in a small town in the Orne, about one and a half months after returning from Lyons, where the disease was prevalent. He was nursed by his wife from the onset of his illness until May 28th, when he was taken to hospital. At the commencement of June the wife contracted a severe form of the disease, which proved fatal within three weeks. As she had not been to Lyons the author considers that she must have been infected by her husband, although she did not develop the disease until forty days after the onset of his illness. Thus the incubation period in both husband and wife was fairly long.

263. Rupture of the Spleen in Malaria.

ACCORDING TO MASSARI (*Wien. Klin. Woch.*, October 14th, 1920), who records an illustrative case in a man aged 23, most of the recorded cases of rupture of the spleen have been discovered only at autopsy. Thus while in some districts of India malarial rupture of the spleen is so frequent that Crawford found 477 examples among 3,884 autopsies, or in 4.45 per cent, reports of cases in which an operation has been performed are extremely rare, which is due to the circumstances of life in the tropics and the superstition and indolence of the natives. Noland and Watson (1913), who during the construction of the Panama Canal operated on three cases of rupture of the spleen among 23,000 malaria patients, state that the patients were able to continue their work for a certain time after the rupture had taken place. In addition to his own case, in which operation was successful, Massari has collected twenty other cases of operation for rupture of the spleen in malaria, 14 of which recovered, and 6 died. The prognosis depends on the rapidity with which the operation is performed after the accident has occurred. Massari concludes by saying that owing to the large number of cases of malaria due to the war the possibility of rupture of the spleen due to a slight trauma should be borne in mind. Patients and their friends should be warned as to the vulnerability of the malarial spleen, and instructions should be given to all first aid stations, police stations, etc., that no time should be lost in obtaining surgical assistance.

264 Chloroma in Infancy.

Rif. Med. (December 4th, 1920), in a review of recent literature on this disease, refers to forty-six cases collected by MENZI, who says that neither heredity, previous diseases, syphilis, rickets, tuberculosis, or injury, play any definite part in the etiology. The classical type arises from the bones of the face or head, causing exophthalmos, visual and auditory disturbances, anaemia, hæmorrhages, ulceration, stomatitis, and death in a few weeks. There is a diminution in the nitrogen, urea, ammonia, and uric acid of the urine. Radiography shows proliferation of the cranial bony tissue, separation of the sutures, areas of rarefaction in the medullary parts of the long bones and raising of the periosteum. These changes help to differentiate chloroma from scurvy, rickets, sarcoma, or syphilis. The blood changes are usually of a macrolymphocyte type with myeloblasts or myelocytes. Prognosis is bad and treatment inefficacious.

265. Melaena Neonatorum Treated with Horse Serum.

FUÀ (*Ref. Med.*, October 30th, 1920) speaks highly of the value of injection of horse serum in the treatment of melaena neonatorum. Excluding spurious melaena from blood swallowed from the nasopharynx or from the mother, and melaena due to syphilis, sepsis, haemophilia, there still remain many cases of unknown origin. But, whatever the cause, horse serum is efficacious. The author briefly records five cases in infants, all successfully treated by injections of horse serum; some of the patients, in addition, had calcium chloride and gelatine, but the effective agent seemed to be the serum. Two or three injections of 10 c.cm. each were given at intervals of twenty-four hours.

266. Arthropathies in Sclerodermia.

ACCORDING TO ADRIAN and ROEDFRER (*Ann. de dermat. et de syph.*, Nos. 6-9, 1920), sclerodermia in rare cases is complicated by changes in the joints which as a rule precede the skin lesions, and only rarely accompany or succeed them. In the absence of skin changes it is impossible to differentiate these arthropathies from other chronic affections of the joints. The age most susceptible to the arthropathies of sclerodermia is that from 31 to 40; the smallest number of cases occurs below 10 years of age. The largest number and the severest attacks are found in the female sex; damp, cold, and chill seem to predispose to the affection. The changes may affect one or more joints, disappear after a certain time, and then recur. In some cases the joints may not undergo any pathological change. In the great majority of cases the onset of these arthropathies is insidious, but in some cases there is an acute onset, in which the joints are painful and tender and the skin covering them is tense and hot. Next to the finger-joints the knee-joint is most frequently affected. The muscles, tendons, tendon sheaths, synovial membranes, and bones may be attacked; in rare cases the heart and thyroid may be implicated. The prognosis is good in the forms manifested by arthralgia only, but is more serious in the cases characterized by progressive affection of several joints and marked deformities. Treatment is usually ineffective.

267. Respiratory Mycoses.

BASILE (*Il Policlinico*, Sez. Prat., October 18th, 1920) states that mycosis of the respiratory system may be regarded as a clinical entity caused by various species of fungi, such as nocardia, monilia, mucor, aspergillus, penicillium, hemispora, oidium, and sporotrichum. The symptoms resemble those of tuberculosis. In moniliasis and oidio-mycosis there is considerable loss of flesh, all the visible mucous membranes are pale, and examination of the blood shows considerable diminution of the red cells and haemoglobin. The patients also have an oral foetor which disappears after treatment. There are no night sweats. The infection may take an acute or chronic course. The average duration of the acute forms is thirty to fifty days, that of the chronic forms varies considerably. The respiratory symptoms and signs consist in pain in the chest, dyspnoea, crepitations, bronchial breathing, and pleural friction. The sputum is profuse and blood-stained. The liver is tender and not infrequently extends below the costal margin. In most cases the spleen cannot be felt. There is anorexia and sometimes diarrhoea. The urine may contain albumin; this is always of grave prognosis. In most cases treatment by iodides given by mouth or by intramuscular or intravenous injection is efficacious, nocardiasis proving the most refractory.

268. The Distribution of Lupus Vulgaris.

WITH (*British Journ. of Dermatology*, October, 1920) states that examination of 900 patients treated at the Finsen Light Institute, Copenhagen, confirmed the old observation regarding the frequency of lupus on and in the nose. In children lupus in this situation was rare compared with lupus in the centre of the cheek, but increased in frequency between the ages of 11 and 16. At this age it was comparatively common on the extremities.

269. Splenomegaly due to Arsenobenzol.

LÉVY-FRANCKEL (*Bull. Soc. de Thér.*, November 10th, 1920) describes two cases of splenomegaly following injections of neo-salvarsan—in a boy aged 13, suffering from lupus, and a soldier suffering from psoriasis; in both the Wassermann reaction was negative. Leukaemia and pseudo-

leukaemia could be excluded by examination of the blood, and the complete subsidence of the splenomegaly negatived the diagnosis of primary tuberculous or cancer of the spleen. Lévy-Franckel therefore concludes that the splenomegaly was due to the arsenobenzol, although no previous cases of this kind have been described.

SURGERY.**270. Acute Orogenic Meningitis.**

SURREAU (*Rev. de l'otol., d'otol., et de rhinol.*, November 15th, 1920), in his Lyons thesis, states that the predisposing causes of acute otitic meningitis are bad hygienic conditions (which were particularly marked during the war), alcoholism, diabetes, adult age, and infectious diseases. Invasion of the meninges occurs (1) as the result of a trauma, the fracture opening a direct path to infection; (2) via the bones of the skull; (3) by rupture of an abscess into the arachnoid cavity. The lesions observed are of three kinds—namely, serous, purulent, and tuberculous meningitis. The purulent sometimes succeeds the serous form. In some cases only a generalized venous congestion is found, in others there are purulent patches, but the disease almost always occurs in persons whose mastoid process contains only a few cells. There is nothing special in the symptomatology, which is the same as that of every other form of meningitis. The clinical varieties are the fulminating form, the acute form (which is much the commonest), and the subacute form, which is very rare. Early diagnosis is important. The condition must be distinguished from the meningism occurring in infectious disease, cerebral abscess, and cerebro-spinal meningitis. Treatment should consist in destroying the infective focus by making a wide trephine opening in the mastoid and temporal fossa, and slight incisions in the dura. Hot baths and lumbar puncture are also to be recommended.

271. Acute Osteomyelitis of the Ribs.

ACCORDING TO FANTOZZI (*Il Policlinico*, Sez. Chir., December 15th, 1920), who has collected 51 cases from the literature, including one of his own, acute osteomyelitis of the ribs is very rare, but is probably more frequent than it appears, as it is very likely that numerous cases have not been recorded, in addition to others which have not been recognized. The organism most usually found is the *Staphylococcus pyogenes aureus* or *albus*. In Loughborough's case the pneumococcus was isolated. In Fantozzi's and Canon's cases the streptococcus was found. The male sex is most frequently affected. The age at which the disease is most often observed is infancy, whereas osteomyelitis in general is most frequently found in adolescence. The seventh rib is most frequently attacked, and there has been no case recorded of the first rib being involved. The clinical and pathological course is the same as that of osteomyelitis in general, the prognosis being favourable, especially when the lesion is limited to the anterior segment of the rib. Treatment is exclusively surgical, indications for operation being the same as for osteomyelitis elsewhere.

272. Diagnosis of Appendicitis.

INDEMANS (*Nederl. Tijdschr. v. Geneesk.*, January 22nd, 1921) records the following case illustrating the difficulties in the diagnosis of appendicitis. The patient was a woman, aged 35, who had suffered for three years on and off from pain in the abdomen, chiefly localized in the right ilco-caecal region and radiating to the loins. On examination of the abdomen a large infiltration could be felt extending upwards above the line connecting the umbilicus with the anterior superior spine and downwards into the pelvis. Vaginal examination revealed a very large tender infiltration on either side of the uterus without any signs of softening. Micturition and defaecation were both very painful. The general condition and pulse were good, and the temperature ranged between 101.2 and 103. A diagnosis of larval appendicitis with circumscribed peritonitis was made, and it was decided to wait and perform an operation *à froid*. Most of the infiltration was absorbed in about ten weeks, and after the temperature had been normal for about a month laparotomy was performed. A dermoid cyst containing greasy material and some pieces of bone was found adherent to the appendix. The appendix itself was 7 cm. long and showed a diverticulum 1 cm. long containing a faecal concretion the size of a cherry stone. The mucous membrane was not ulcerated, but only in a catarrhal state. The symptoms of circumscribed peri-

tonitis were probably not due to the appendix, but may have been caused by irritation of the peritoneum by torsion of the pedicle of the dermoid cyst.

273. Autotransfusion for Haemorrhage.

LOVE (*Med. Record*, January 8th, 1921), acting upon Lewishon's observation that the coagulation time of the blood could be reduced even by autotransfusion (300 c.cm. autotransfusion on a dog reducing the normal coagulation time of five minutes to ten seconds), obtained similar results in eight dogs experimented upon. After applying a tourniquet above the field the vein is punctured with a short needle and blood aspirated into a 10 to 20 c.cm. syringe to the capacity of the syringe. The tourniquet is released and, without disconnecting, the blood is injected back again. The process is repeated in one or two minutes until the total amount withdrawn and reinjected equals an ordinary transfusion. Two syringes are required, so that they can be changed about every five minutes, 0.5 per cent. sodium citrate or normal salt solution being used for rinsing the syringes between use, and at each change of syringe about 2 to 5 c.cm. of physiological salt solution should be injected to ensure a clean needle. Although the bleeding time and the coagulation time are not related in any simple manner, the experiments on bleeding time showed that wounds which would ordinarily have bled very severely, were quite easily controlled after autotransfusion. All the experiments were upon normal blood, so that the adaptability of the method for haemorrhage in cases with an abnormal coagulation time is yet undetermined.

274. Fatal Asphyxia from Food-block.

Il Morgagni (December 15th, 1920) draws attention to two groups of cases of sudden death associated with meals: (1) Those in which, on unvoiced exertion or sudden emotion after a full meal and with a stomach loaded with food, death occurs suddenly; these are usually associated with status lymphaticus or some disorder of the endocrine system, and as a rule treatment is impossible and useless. (2) Cases where death is due to the impaction of food in the pharynx, causing suffocation. Six such cases are recorded, and in only one was the cause recognized, and although the man was supposed to be dead when seen by the doctor, the idea arose in his mind to put his finger down the throat, when he pulled out a mass of food, and after respiratory exercises were started the man recovered. The suspicion of food impaction being the cause arose from the observation that on trying artificial respiration no air was found to enter, and on examining the pharynx the mass of food was discovered. If this possibility were thought of in similar cases some lives might be saved.

275. Experiments on Temporary Exclusion of One Kidney.

MIN-AZZINI (*La Clin. Chirurg.*, May-June, 1920) has carried out a series (75) of operations on thirty-three dogs—excluding the ureter for about half an hour and measuring the urea excreted by the other kidney before, during, and after the exclusion. The author found that compression of the upper half of the ureter either has no influence on the function of the other kidney or acts as a stimulus to the contralateral organ. Exceptionally the renal activity may be lessened. But when the lower half of the ureter is compressed, the activity of the other kidney is always lessened, and in some cases if the ureter was compressed near the bladder, anuria resulted. From these experiments and a study of others, the author suggests that temporary closure of the ureter near the kidney may be useful as a preliminary stage to nephrectomy in those cases in which it has not been possible to get the urine of the two kidneys separately.

276. Division of the Superior Laryngeal Nerve in Laryngeal Phthisis.

MAYER (*Wien. Min. Woch.*, January 6th, 1921) has carried out division of the superior laryngeal nerve on both sides for relief of dysphagia in ten cases of advanced laryngeal tuberculosis in which all other methods had failed. The operation in each case was performed under local anaesthesia. The result in most cases was very good. In two cases who survived for a considerable time there was a distinct increase of weight directly after the operation, and in a larger number the weight, which had hitherto been rapidly falling, remained constant. Most of the cases, however, survived the operation only a short time, the period of survival ranging from fourteen days to four months. In two the operation was not successful, as, in spite of complete division of the nerves, the dysphagia persisted, this being obviously due to the ulceration extending beyond the distribution of the superior

laryngeal nerve. Mayer's general impression of the operation is that it is more efficacious than the injection of the superior laryngeal nerve with alcohol, as recommended by Hofmann.

OBSTETRICS AND GYNAECOLOGY.

277. Varicose Veins of Female Pelvis.

EMGE (*Surg., Gyn., and Obstet.*, February, 1921) states that varicose veins of the pelvis are always acquired, and that while intestinal ptosis, habitual constipation, and prolonged menses may all produce them, pregnancy is the most important factor. The symptomatology centres round the pains the patient has complained of, which, beginning with a definite time, have appeared either bilaterally or unilaterally, usually on the left side, of a dull deep aching character, deep down in the abdomen, growing worse on long standing, and relieved quickly when the patient assumes the recumbent position. Other symptoms, such as constipation, leucorrhoea, backache, gastric disturbances, are not definite. If the patient is examined in the recumbent position the varicose veins are not palpable, and the diagnosis should be made by recto-vaginal examination in the recumbent alternating with the sitting position, the patient dropping her legs and raising the upper part of the body. In regard to treatment, the patient should keep off her feet as much as possible, and sexual excitement should be prohibited. Hot douches are of no benefit, but slow lukewarm douches with 2 to 3 per cent. menthol and 5 per cent. alum, will produce a pleasant cooling effect; 10 per cent. ichthyol vaginal suppositories, every night over two to three months, undoubtedly help. When the veins are so distended that one cannot suppose they can return to normal, operative procedures must be considered, and Emge says that resection of the veins is unnecessary, but that a high suspension of the uterus with a shortening of the uterosacral ligaments offer the best means of symptomatic cure, with a possibility of a permanent anatomical regulation.

278. An Unusual Case of Galactorrhoea.

LUZZATTI (*R. Policlinico*, Sez. Prat., December 13th, 1920) records the case of a primipara who, in the fourth month of pregnancy, developed a profuse discharge from the nipples, the fluid having the characters of colostrum. The discharge caused irritation of the nipple and surrounding region with the formation of superficial fissures. The galactorrhoea continued during pregnancy and after the birth of the child, and was so profuse that in twenty-four hours more than two litres of milk could have been collected. By the fourth month of lactation the continued drain on her system gave rise to prostration, headache, and persistent dorso-lumbar pain. Sedative and astringent ointments were applied to the nipples, and when the fissures had healed the galactorrhoea ceased, after it had lasted for ten months.

279. Puerperal Thrombosis of the Vagina.

CHARBONNEL and FAYREAU (*Gaz. hebdomadaire des Sci. Méd. de Bordeaux*, January 30th, 1921) state that puerperal thrombosis is an unusual occurrence, being met with in only one out of 3,000 deliveries, and that it is extremely rare for it to become infected. According to Champeau, only 18 cases of thrombosis occurred among 54,000 women delivered in Professor Finard's clinic, and in none of these 18 cases did infection take place. The writers record a case of puerperal thrombosis of the vaginal wall in a primipara in which infection occurred forty days after delivery. It was uncertain whether the infection was caused by a vaginal erosion, by the lymph or the blood stream, as the patient had a slight attack of mastitis.

280. Diagnosis of Foetal Hydrops Universalis.

KAFKA (*Zentralbl. f. Gynäk.*, November 20th, 1920) records a case of protracted labour in a multipara who gave birth to a child showing ascites and oedema of the extremities. The foetal heart sounds had been audible with special clearness in all parts of the enlarged uterus, and the author suggests that this finding may be of significance in the differential diagnosis from hydramnios—a condition in which the heart sounds are relatively indistinct.

281. Injections of Milk in Puerperal Infections.

BIANCHI (*Rif. Med.*, November 6th, 1920) reports favourably of the treatment of puerperal infections by injections (mostly intramuscular) of milk. In 16 cases the milk was

injected as a prophylactic and in 57 as a curative agent. The results were as good as those previously noticed after injection of specific serums, and in the author's view were sufficiently encouraging to warrant further trial. Cow's milk was used and given in doses of 5 c.cm. to 20 c.cm. either every day or on alternate days. Usually three injections were given, sometimes five. The effect on the blood was to produce an initial leucopenia, followed by hyperleucocytosis.

PATHOLOGY.

282. Complement Deviation in Surgical Tuberculosis.

MOZER and FRIED (*C. R. Soc. Biologie*, December 18th, 1920) report on the results of the complement fixation reaction with Besredka's antigen in 689 cases in the seaside hospital at Berck. These comprised 173 cases of Pott's disease, 136 cases of coxalgia, 83 white swellings of the knee, 105 other tuberculous osteo-articular lesions, 44 cases of tuberculous glands, 105 rachitics, 16 cases of congenital syphilis, and 27 others of non-tuberculous nature. In Pott's disease of under three years' duration gave positive results, and of those over three years' duration were positive; when fistulae were present the percentage of positive results fell to 26. In the coxalgias under three years' duration 75 per cent., over three years 28 per cent., and where fistulae existed 24 per cent., were positive. In white swellings of the knee of less than two years' duration 76 per cent., and over that time 36 per cent., were positive, whilst the fistulous cases gave successful reactions in 14 per cent. In other articular tuberculous lesions 70 per cent. were positive when the disease had existed for less than two years, and 34 per cent. when they were long-standing. In tuberculous adenitis the reaction was positive in 36 per cent. In all the tuberculous cases, with very rare exceptions, the anti-reaction with tuberculin was positive. In the pure rachitics 7.5 per cent. gave positive complement deviation results; in the non-tuberculous cases of hereditary syphilis 50 per cent. gave positive reactions with the antigen; and in the various other non-tuberculous diseases only 2 were positive amongst the 27. Two striking results stand out: the percentage of positive results is much higher in cases of developing tuberculosis than in those undergoing cure; and the formation of fistulae corresponds with a feeble percentage of positive reactions.

Eosinophilia in Scabies.

283. HAYMAN and FAX (*Arch. Derm. and Syph.*, January, 1921) examined the blood of 55 scabies patients, varying in age from 3 to 30 years. The largest number of eosinophiles found was 15 per cent. and the smallest 1 per cent., with an average of 5.5 per cent. Thirty-two cases (58 per cent.) showed 5 per cent. or more of eosinophiles, whilst twenty (36.6 per cent.) showed 7 per cent. or more. The higher percentages came from the more extensive infestations, and the low or normal counts either from very recent cases and the low or normal counts had been noted for only two or three in which symptoms had been noted for only two or three days, or else from slight infestations. The presence of pustules did not seem to be a factor. The eosinophilia increased with the extent of the disease and disappeared promptly as the disease was cured. Observations were made in order to find if, in addition to the blood eosinophilia, there was a local eosinophilia in the neighbourhood of the lesions, but no important difference was found.

Osteitis Mastoideo-zygomatice.

284. LUND (*Hospitaltidende*, January 5th, 1921) discusses the pathology and frequency of otogenic subperiosteal abscess in the temporal region. In a few cases an abscess in this position can be traced to inflammation of the cancellus tissue of the root of the zygomatic process. The author records two cases illustrating this comparatively rare condition. Although there was disease of the mastoid process in both cases, the inflammation of the root of the zygomatic process did not coincide with that of the mastoid process; indeed, in one case there was an interval of almost a year between the operation for mastoid disease and the development of an abscess above the external ear. In both cases the pre-existing disease of the middle ear and tympanum had apparently cleared up altogether. But the condition should still be regarded as a propagation of an inflammatory reaction from the mastoid process and middle ear upwards to the zygomatic process. The signs were, upwards in front of the ear and in the temporal region, swelling in front of the ear and in the other case pain on mastication.

285. Changes in the Heart and Circulation due to Muscular Exercise.

BARLOCCO (*Rif. Med.*, October 30th, 1920), as the result of a series of observations, finds that the normal subject after moderate exercise shows a slight reduction in the size of the heart, as well as an acceleration of pulse and increase of systolic blood pressure, both of which quickly regain their normal level. In the patient with compensated cardiac lesion there may be either a similar reaction or some increase in the cardiac diameters and changes in the pulse and pressure such as are seen in the early stages of the disturbed vascular equilibrium. In the neurotic vagotonic cardiac subject, after moderate exercises, the cardiac and pulse changes may be the reverse of what occurs in the normal subject. In the neurotic cardiac patient who suffers from changes in the sympathetic system, either no change or some reduction in the cardiac size was noted. After hypodermic injection of adrenalin a slight increase in cardiac volume and in systolic and diastolic pressure was found to occur. If the knee was flexed twenty times during the adrenalin period a reduction of the cardiac diameter could be well seen. In the vagotonic subject no increase in cardiac volume was observed after injecting adrenalin; in the sympathicotonic a marked increase in systolic and diminution of diastolic pressure was noticed. After hypodermic administration of 0.01 gram pilocarpin, diminished pulse rate and systolic pressure, increased cardiac volume, and great difficulty in performing exercises, were noted in the vagotonic; the reverse occurred in the sympathicotonic subject.

286. The Blood Pressure and Oedema in Hemiplegia.

MIRALLIÉ (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, July 1st, 1920) examined the blood pressure, using Pachon's instrument, in twenty cases of hemiplegia, sixteen of which were in women and four in men; the duration of the hemiplegia ranged from seven months to thirty years. As a general rule he found that the maximum tension was lowest on the paralysed side both in the upper and lower limbs, whereas the minimum tension was practically equal on both sides. From a study of three cases the writer concludes that oedema, whether early or late in hemiplegia, is due to cardio-renal inefficiency. Hemiplegia, by disturbing the blood pressure, produces a slowing of the local circulation, and gives rise to the immediate appearance of a hitherto potential oedema. The existence of a purely nervous oedema has yet to be proved.

Glycosuria in Infants.

287. USING the test of Benedict and Osterberg, GREENTHAL (*Amer. Journ. of L.S. of Children*, December, 1920) has found that the urine of all normal infants contains a determinable amount of reducing sugar; the amount of sugar excreted is proportional to that ingested. As the amount of sugar in the diet is increased the total sugar in the urine becomes greater, but the increase chiefly concerns the fermentable portion. When the intake of sugar is constant, sugar excretion both as regards the fermentable and non-fermentable portion, is also fairly constant. In infants receiving from 6 to 7.5 per cent. of sugar the total sugar excretion in the urine ranged from 100 to 400 mg. a day. Benedict, Osterberg, and Neuwirth found that on an ordinary diet adults excrete from 600 to 1,200 mg. of sugar a day.

288. Provocative Reactions in the Cerebro-spinal Fluid in Neuro-syphilis.

SOLOMON and KLAUDER (*Arch. Derm. and Syph.*, December, 1920) give case-histories to show that after treatment by arsphenamin the cerebro-spinal fluid, which was negative before treatment, may become positive in all routine tests, or a weakly reacting fluid may become much stronger. This "provocative reaction" may be evoked by intravenous or intraspinal injection of arsphenamin; it is comparable to the provocation of the Wassermann reaction in the blood and to the Herxheimer reaction (production of neuro-réurrences). The provocative reaction is shown to occur in both the ventricular and spinal fluids. It is not a frequent phenomenon, and patients with vascular neuro-syphilis with negative cerebro-spinal fluids may not react in this manner: by the reactions, however, diagnosis may occasionally be made clear in obscure cases. In none of the cases in this series was the provocative reaction obtained with the blood serum. Despite the increase in the strength of the spinal fluid reactions, clinical improvement may result, and continued treatment may again produce a negative fluid.

A British Medical Association Lecture ON THE INFLUENCE OF THE WAR ON THE MODERN TREATMENT OF FRACTURES.*

BY
HENRY WADE, C.M.G., D.S.O., M.D., F.R.C.S.Ed.,
EDINBURGH.

THE experience which so many doctors gained when serving with the army in the field has not only modified profoundly the method of treatment of cases of fracture and other injuries, but has also changed in a marked degree our outlook on many of the general problems that confront the medical profession.

The first and most important lesson learned was that the treatment of the injured was never the concern of one single individual. It was always the joint responsibility of a team, each member of which loyally co-operated to contribute his share towards obtaining the most painless and most speedy cure of the sufferer. The responsibility for the care of the wounded man commenced on the firing step or even in the field in front of it where the soldier fell, and continued up to the time of his final cure. Let us trace his progress through the various stages of his treatment and see what lessons, useful to civil practice, we can learn thereby.

The regimental medical officer was the family doctor of his battalion. His duties, as regards the care of the wounded, commenced long before his battalion went into action or even entered the line. When on home service there was detailed to him a group of men selected usually by their company commander or squadron leader as unlikely to make efficient soldiers. These were appointed battalion stretcher-bearers and wore the S.B. brassard on their arms. At this stage in their existence they were looked on by the combatant ranks as a necessary nuisance, which unfortunately decreased further the bayonet strength of the firing line. But later the actual experience of warfare altered this opinion, and the quiet heroism they displayed, and only too often the heavy casualties they endured, made them the most respected and admired soldiers in their battalion.

The value of the instructions imparted by the regimental medical officer to his pupils was at first frequently not very apparent when it came to be tried in actual practice, but, in the later stages of the war, some of these bearers became so expert in applying dressings to recent wounds, and in treating such serious injuries as fractured femurs, that their service to the battalion was of the very greatest value. The neatness, expedition and comfort with which they carried out this treatment few medical men could equal.

When confronted with the problem of the treatment of the recently wounded, the duties of the regimental medical officer were clearly defined. They were: to cover the wound to prevent it being further contaminated, to relieve pain, to arrest haemorrhage, to provide rapid and comfortable transport, and to minimize shock.

The success which attended their efforts to minimize the shock following a serious wound was found to depend to a great extent upon the thoroughness with which pain was relieved, haemorrhage arrested, and rapid and comfortable transport provided. The history of the treatment of gunshot fractures of the femur as it evolved during the war illustrates this.

FRACTURED FEMUR: THE THOMAS SPLINT.

In the earliest stages of the war the battalion medical officer relied almost entirely on the application of a rifle splint to immobilize a fractured femur. To apply this correctly is difficult, and when applied it has many disadvantages. The patient is difficult to transport; the result is on the whole unsatisfactory. When he came under the care of the field ambulance at its advanced dressing station, or farther back, the rifle splint was removed and a Liston's long splint substituted, but little

improvement was obtained, and latterly the use of this splint was generally emphatically condemned.

The mortality that attended cases of fractured femurs was at this period appallingly high. Statistics, collected over part of the army area in France in 1916 by Colonel Sir H. M. W. Gray, led him to estimate the total mortality at nearly 80 per cent., a large portion of it being at the casualty clearing station or on the way there.

The battle of Arras, which took place in April, 1917, was about to be fought, and Colonel Gray, being convinced that a great saving in life might be effected in these cases by the use of the Thomas splint as a routine method of fixation, instituted a well organized educational campaign through the medical men of the Third Army to achieve this object. With the knowledge and approval of General Allenby this was carried out. A good supply of Thomas splints was distributed to the field ambulance, and even farther forward, and orderlies were trained to put these on. The result was that cases, instead of arriving at the casualty clearing stations almost moribund from shock and exhaustion, came in well enough to stand immediate operation, and the death rate in the clearing station of one army actually fell from nearly 50 per cent. in 1916 to 15.6 per cent. in 1917.

At that period I was serving as consulting surgeon with the army in Palestine. We knew of the Thomas splint, and were advocating its more widespread employment with partial success, but soon thereafter there arrived in the East the greatest benefactor the surgery of the army there received—General Allenby took over command. At one of his earliest conferences, I am informed, when the medical organization for his forthcoming offensive was being reviewed, he said that he believed there was a splint known as the Thomas splint, which was invaluable in cases of gunshot wounds of the thigh or knee, and it was his intention and desire that there should be one such splint available for every soldier receiving a wound in this region. The driving power behind this decision was magical. The central splint factory in Alexandria, which at the time was completing an order for 2,500, received instructions to make 5,000. Every general hospital, stationary hospital, casualty clearing station, and field ambulance was encouraged to equip itself with them. The regimental medical officer carried them with his field equipment. The field ambulances had them strapped to their sand carts. Every advanced dressing station was well equipped with them, and a report was called for on any case of this nature that came back from the advanced dressing station without one having been applied.

The most valuable illustration of the benefit to the patient of the Thomas splint for the treatment and transport of the fractured femur, that I observed, was during the fighting beyond the Jordan and hills of Moab. This took place at the beginning of 1918, and consisted of raids carried far into enemy country. During the fighting at Amman roads were virtually non-existent, and it was found almost impossible to bring up the guns, and still from here men with fractured femurs were successfully transported twenty-five miles on camel-back or in limbers, and a further thirty miles in light Ford ambulances to the banks of the Jordan, where, at the corps main dressing station, they were dealt with by the advanced operating units.

The principles underlying the use of the Thomas splint are few, simple, and easily carried out, but, of course, the circumstances under which it is used were found to modify the method in which it was employed.

For in the East a standard outfit was manufactured at the R.A.M.C. central splint factory in Alexandria. The aim underlying this outfit was to have one that was portable, and easily and rapidly applied. The rules that were laid down were that whatever method was employed, the extension must be maintained during transport. The ring of the Thomas splint must press against the ischial tuberosity and never slip over it. The lower end of the Thomas splint must be hung but not fixed to the lower stretcher bar. A suitable footpiece supports the foot.

The lesson the war taught us as regards the arrest of haemorrhage, when met with in a case of compound fracture, or occurring independent of that injury, undoubtedly was the danger attending the use of the tourniquet. To allow a patient to whose limb a tourniquet had been applied to pass out of your sight or, worse still, from

* Abstracted from a lecture delivered before the Fife Branch at Kirkcaldy on December 5th, 1920.

under your care, came to be looked on as a professional disgrace. The advice we gave to the regimental medical officer dealing with a case of severe bleeding from a recent wound, and to the field ambulance officer doing duty in a crowded regimental aid post, was, in all cases where bleeding would not cease from a natural arrest, or could not be controlled by the local pressure of a shell dressing, to grasp the bleeding points with pressure forceps and send the patient down with these haemostats attached to his wound.

A story illustrating the application of this method is of interest:

As day was dawning on the morning after the first battle of Gaza there was brought to the 44th Casualty Clearing Station, then situated north of the village of Khan-Yunis, a convoy of wounded from a field ambulance. The most serious case in it was brought direct from the sand-cart into the operating tent, and there came under my care. The patient was an officer of the Royal West Kent Regiment, who had been shot in the neck, the bullet having penetrated his chest and wounded the dome of his right lung. He arrived with two artery forceps projecting from the wound above the clavicle, and his field card informed us that the internal jugular vein had been wounded and the bleeding from it arrested by the application of pressure forceps. The wound was excised, the torn vessel ligatured, and the wound in the pleura and skin closed, and later on he was sent down the line. Some months afterwards I was asked to forward particulars concerning his case, and in reply received from a senior officer of the R.A.M.C., holding a responsible administrative post at the base, a letter thanking me for the services I had been able to render to his nephew, who had been my patient and had now rejoined his regiment. I was asked to transmit to the officer of the ambulance an appreciation of the deep debt of gratitude he had earned for having saved his nephew's life. This I did, and was amused to be shown by that field ambulance medical officer a copy of the correspondence he had recently received asking him to account for the loss of two pairs of artery forceps, for the replacement of which he was held personally liable.

For the transport of cases of fracture of the femur, or injuries involving the region of the knee-joint, or in fact any case of fracture of any of the bones of the lower extremity, the Thomas splint sufficed. Up to the end of the war considerable difference of opinion existed as to the most suitable splint for fractures involving the bones of the upper extremity. From the many splints that were available and used for this purpose, I would recommend most strongly one which is easily and rapidly applied, and permits of the patient being transported in the greatest comfort—namely, the Hey Groves wire cradle arm splint. With this in your possession—and any blacksmith can make it for you in a few minutes—you require nothing more.

The transport and treatment of the case of shattered hip, pelvis, or spine is always difficult, and for such cases a Jones abduction frame is a priceless aid. It is awkward to carry, and the case for which it is suitable may be long in coming under your care, but if available when required it will be found of very great value, and contribute largely to the saving of life.

WAR LESSONS IN CIVIL PRACTICE.

The application of the experience gained by the regimental medical officer and his colleague to the problems met with in civil practice merits consideration. The regimental medical officer was the keystone of the successful medical service in the field. He knew it and was proud of it. Contrary to the regulations, he proudly wore the bonnet of his battalion, or the badge of his regiment, and wherever his men went there he was to be found. Prompt attention and prompt transport were his guiding principles, and in doing these well he did the greatest of the many services the wounded man received.

The general practitioner of medicine is the regimental medical officer of the industrial army, and the solution of many of the most fascinating problems is in his care, where recent injuries have to be dealt with. For example, what arrangements exist for the supply of Thomas splints to the coal pits in our neighbourhood? Where are they to be found at the pit bottom? Who is trained in applying them? Can the arrangements for the transport of the miner with the broken back from the coal face, where he has been hurt, to the pithead be improved?

If our civil advanced dressing station be an office at the pithead, or a neighbouring miner's cottage, the question of its equipment may be put to you. Drugs and dressings we will never forget, but what is of greater value is likely to be absent. If you receive the offer of help that I did when

stationed with my unit at Suria Bay on the Gallipoli peninsula, I would advise you to reply, as I wired back, "Send sponges, rubber hot-water bottles (the army called them stomach warmers), and clean pyjamas." If you can deliver your case of fracture clean, warm, and with the fragments well splinted within four hours at corps main dressing station, you have done the best for your patient, even although the wound is uncleansed.

Most of the popular glamour of military surgery was focussed on the corps main dressing station, where the advance operating units worked, or on the casualty clearing stations in France, where these formed the forward surgical centres. The patient having arrived in a suitable state for operation, the first problem was the disinfection of his wound. The evolution this process underwent is of interest. Chemical disinfection was at first mainly relied on, and when the antiseptics in common use failed, new ones were invented. Watson Cheyne introduced an antiseptic paste with which the wound was filled, with results that proved unsatisfactory. Eusol was found of value, and the Dakin-Carrel method of treatment was employed. Of the latter it may be said, as was once remarked of socialism, it would be an ideal practice in an ideal community, but in an ideal community it would not be required. Something less exacting in its demand on the time of the staff, something less fool-proof was wanted. Then came the saline tide. The introduction of chemicals from without having failed, we turned to a method whereby, with the aid of salt solutions, we flooded the wound with antibodies from within, normal saline solution, hypertonic saline solution, and salt packs being used. Many were cured by this method, and several had serious secondary haemorrhage in consequence of it.

Finally the old adage was remembered, that the best of all antiseptics was the healthy tissues, and the excision of wounds was practised, all the unhealthy damaged tissue being cut away and the wound closed or united later by secondary suture. The many brilliant results that followed this line of practice must not, however, upset our temperate judgement. Many wounds will be found where complete excision of the damaged tissues is an anatomical impossibility. Others will be met with already seriously infected. For these cases two remedies were found of great value, one bipp and the other flavine.

Bipp and Flavine.

The use of bipp, or bismuth iodoform paraffin paste, was condemned as harmful by a number of surgeons with wide experience in the treatment of the wounded. In many cases, however, when the grounds for their criticism were reviewed, it was found that the method that had been employed in using the remedy was not that advocated by the originator of this line of treatment, Mr. Rutherford Morison, but that, contrary to his advice, a large quantity of it had been left in the wound, subsequently giving rise to harmful consequences. Some seem to have employed it as they would Beck's paste, filling up the entire cavity, with it, and even thereafter closing the wound. Naturally the tissues resented such a foreign body containing irritant chemicals and endeavoured to expel it in the abundant discharge that resulted.

In the later stages of the war bipp was used in many cases in the Egyptian Expeditionary Force, and we found it to be of great use in many of them. Owing to the nature of the military operations that were being carried out, where the wounded had nearly always to be treated many miles from rail-head, and in all cases had to be transported through most difficult country before reaching the forward casualty station, or the hospitals on the lines of communication, it was frequently the case that the patient could not be re-dressed within twenty-four hours. When Damascus was captured the wounded were then nearly 400 miles from rail-head.

Where the wound was already infected, or where complete excision of it could not be practised, and the surgeon was compelled to leave behind a certain amount of devitalized tissue, the use of bipp was found of great value. It was possible in such a case to transport the patient in comfort and in safety, leaving the wound undressed for several days. Frequently his temperature was raised above normal, his pulse quickened, and a sero-purulent discharge escaped from the wound, which was swollen and somewhat oedematous, but it was noticeable how little pain he suffered. He slept well, his appetite was good, and later the wound was found to heal rapidly. The method employed was to cleanse the wound thoroughly of all

débris and damaged tissue, completely arrest all bleeding, and then disinfect it with spirit, after which a very small quantity of bipp was rubbed carefully into every corner of the wound, any slight excess that remained being carefully wiped off so that none remained visible at the end of the application. The wound was then packed, or in certain cases closed, and a spirit dressing applied.

The most astonishing results that were obtained by the use of bipp were in cases of gunshot wounds of the knee-joint resulting in acute suppurative arthritis.

Our experience with the use of flavine was interesting. At first from a study of the literature it appeared to us that at last we had here provided for us by Carl Browning the ideal antiseptic. It was non-toxic; it was virtually non-irritant. At first it might be employed in a strength of 1 in 1,000, and for subsequent treatment in a strength of 1 in 5,000. Instead of losing its potency when diluted in the serum of the tissues this was enhanced.

Our experience with the original consignment and with what we obtained later was similar to that of other observers—that it was a remedy with peculiar limitations. We found it an excellent remedy for picking the wound. The wound remained remarkably dry, quiet, and irresponsive. The process of suppuration and the process of repair both seemed to be in abeyance, and it was found advisable to substitute, after it had been used for a few days, another remedy such as eusol or saline solution, when the wound then actively responded and healing took place rapidly. It will be thus observed that flavine found its greatest sphere of usefulness in cases where there was much damage of tissue which had to be transported long distances.

The lessons applicable to civil practice from these experiences appear to me to be the importance of early operative treatment in the case of a recent wound, such as a compound fracture, and the value of practising primary excision in these. If the tissues are extensively damaged and this cannot be practised, or if the wound is already infected, I would advocate that it be bipped, or, if the patient is to be transported out of your personal care, that it be packed with gauze soaked in flavine solution in the strength of 1 in 1,000.

GUNSHOT FRACTURES IN BASE HOSPITALS.

There are few who will deny the contention that one of the most brilliant achievements in the history of modern surgery is the record of the treatment of gunshot fractures as carried out in the base hospitals in the later stages of the war.

Many factors detrimental to success were present. Pearson and Drummond estimated that there were 5,000 new femur cases in the British army in France alone in the last nine months of the war, and this may be estimated to form only about 5 per cent. of all the casualties that had to be dealt with. Imagine the situation! Hospitals overcrowded at a period when they were being bombed during the night—so much so that some had to be moved and all patients evacuated and transported to England. For the 5,000 cases mentioned only a limited staff was available, and finally the class of injury that had to be treated was one where almost every one differed in some detail in its nature and required careful individual attention, and at any moment it was liable to provide you with that ghastly surgical tragedy—a severe secondary hæmorrhage. And still the end results were uniformly brilliant.

Some will naturally seek for an explanation of this success in some new apparatus or new form of operative treatment that was employed. They will certainly discover that the young military surgeon invented and improved many articles of great use in dealing with such cases. These appliances all had this characteristic, that they further improved and simplified the immobilization of the fractured bone and at the same time further mobilized the patient.

The Balkan frame or Balkan bed that was extensively employed by them permitted the limb to be immobilized in any attitude desired, especially with the limb abducted. It also allowed of the patient raising himself in bed and even assuming the sitting posture, and, when the knee flexion piece was attached to the Thomas splint, flexion of the knee-joint could be practised daily without interfering with the maintenance of continuous extension. To obtain this extension Pearson's callipers, which

grasped but did not penetrate the condyle of the femur, were especially beneficial and permitted of direct and accurate extension being carried out in a manner simpler and safer and over a longer period than did a Steinmann's pin. At the same time I must confess that my experience in the use of Steinmann's pins for transfixing the femur appears to have been unusually fortunate, for, out of over a hundred cases in which I have seen it employed, I cannot remember one case that was followed by serious after-consequences due to its use.

In many cases Sinclair's glue proved of value, and for fractures in the region of the ankle his skate was of great assistance. The properly designed fracture bed with the bismit and half-bismit mattress helped most materially to increase the patient's comfort.

The possession of all these, however, was not the secret of the success obtained. This was mainly to be found in the whole-time staff of medical men, nurses, and orderlies that carried out the treatment. A continuity of policy could thus be practised, a standardization of the principles of treatment obtained, and the end-results observed by the keen and devoted team of workers who had cared for these cases. In other words, the cases were concentrated; the men anxious to treat them got them to look after. They had time to do so, and saw the final result.

The application of the knowledge to be gained from these experiences to civil practice is worthy of our careful consideration. To begin with, we start with this advantage, that most of our cases are much easier to treat, being simple fractures with unbroken skin. At a moderate cost a complete outfit can be obtained for treating a case of fractured femur. The simplest and best bed frame, in my experience, is the Morison R.I.E. bed-frame. Its invention is the outcome of the application of the wide knowledge of Sir Harold Stiles' late resident, Dr. Abbott, now of Ann Arbor in America, by Mr. Morison, engineer to the Royal Infirmary, Edinburgh.

The complete outfit should include a knee flexion piece for attachment to the Thomas splint and pressure pads for correcting local lateral displacement. A pair of Pearson's callipers and a pot of Sinclair's glue will complete our essential equipment, but a bent Thomas splint and a Sinclair's skate will be found most useful for treating fractures of the leg, whether simple or compound.

Even when all these were available, I have seen in a military hospital, and, more recently, in civil practice, a lamentable failure attend the treatment of a simple, straightforward case. Let us be frank and discuss the reason. Is it not to be found mainly in a disinclination or a lack of sufficient time to treat these cases on the part of the surgeon in attendance? Is it not true that in most hospitals the recently appointed house-surgeon, or even the surgeon in charge, estimates the luck of the waiting day, on the following morning, by the number of cases of fracture that have not been admitted? He much prefers that vacant beds should be available for the admission of cases requiring operative treatment where the problem to be dealt with is rapidly solved in the operating theatre, and little further is required but hasty observation of his patient's progress.

In so many hospitals the visiting staff have not time to devote to the proper care and treatment of fractures, and in nearly all hospitals the tenure of office of the house-surgeon is so brief that his period of service has almost expired before he really understands how to deal with such cases, and he relinquishes his appointment in favour of one who in his turn has to be trained.

I do not suggest that great skill or dexterity or prolonged study is necessary to treat cases of fracture. All that is required is a devotion to this branch of surgery by one who has the time and enthusiasm to carry out carefully daily observations on the progress of his patients and note the faults at their inception, when they are usually easily corrected. The fundamental principles underlying this practice are few, simple, and easily understood.

In military surgery, when the patient was discharged from the general hospital he was transferred to a convalescent dépôt. On the whole he had a very good time there. He had ample opportunity for rest and relaxation, and its environment was usually such as to encourage him to be out and about, and games suitable for his crippled state were usually provided. From this hospital he was transferred to the command dépôt, and on the day of his admission graded in his suitable class. If seriously crippled

he would be put in the fourth class and looked after by a medical officer. The officer in charge of the dépôt was a combatant, but no patient could be transferred from his class to a higher one without the approval of the medical staff. Ultimately, as he gradually improved, he would reach the first class, where he was capable of carrying out regular exercises, usually in the form of specially designed games, and also certain duties, such as mounting guard and light fatigues. Before he returned again to his regiment he was boarded, and the final result of his treatment was not judged by what he who originally operated on him thought, but by the cold light of the end-result obtained. The question then was, Can he wear his equipment? Can he march five miles with his pack? Can he do the full and arduous duties of a soldier of the line? And if so he was considered a Class A man.

The lessons we learn from this are of course extremely difficult to apply to civil practice in our democratic community, but I am sure that there is here a great field for improvement in our surgical work. Rigid and compulsory training or exercises are sought for by no civil surgeon that I know of, but the harmful effects of their absence are seen in almost every compensation case following injury. A very great deal, I am sure, can be obtained voluntarily, and if the facilities existed and their benefits were demonstrated in the case of a few the great majority would soon seek to participate in them.

ECONOMIC ASPECT OF FRACTURES.

The economic importance of the treatment of fractures is realized by us all. The injury is usually met with when the patient is at the height of his wage-earning capacity and has the responsibility of a household and family dependent on him.

The issue of the BRITISH MEDICAL JOURNAL of November 30th, 1912, contains the report of the British Medical Association Committee on the treatment of simple fractures:

In Table VII, which deals with all fractures occurring in patients over 15 years of age, those treated by non-operative measures were 1,324; their average duration of incapacity was 27.6 weeks. The number of cases in which the incapacity was permanent was 121, or 9.02 per cent. There were 179 cases of fracture of the shaft of the femur, the average incapacitation being 33.6 weeks, and the number of cases in which incapacity was permanent was 21, or 11.7 per cent.; 673 were fractures of the shaft of the tibia and fibula, the average number of weeks of incapacity being 26.7; 41 of these were permanently incapacitated, that is, 8.1 per cent.

Recently I discussed with a large employer of labour the question of hospital organization and the economic importance of the treatment of fractures in the industrial world, and he was kind enough to give me access to information bearing on the financial side of this question.

I have been provided with a consecutive series of 22 cases of workmen who in the year 1917-18 suffered fractures of the bones of their lower extremities in the course of their work. Of these, 7 were fractures of the thigh, 14 fractures of the leg, and 1 was a fracture of the thigh and leg. To these £2,932 11s. 5d. was paid in compensation, and out of the 22 fractures, 14 exceeded a period in which their recovery might be fairly anticipated. It is estimated that the extra compensation paid by the employer in consequence was £1,553. It is also estimated that the financial loss to these 14 men amounted, even after crediting them with their compensation, to £3,663, the total loss being thus £5,221, a sum which appears even more impressive when capitalized as an annual charge at 6 per cent., when it amounts to £37,000.

I do not say these figures are accurate and beyond dispute. No statistics are. The important feature of them, however, is that they are considered so by the person who has provided me with them. According to the information possessed, he and his fellow masters of a great industry believe, apart from humanitarian grounds, that there is value to be obtained by themselves, their employees, and the State from good surgery. Their deliberate conclusion is that, when calculated on the 1918 basis—which, of course, is much lower than now holds good—a sum up to £5,221 may economically be expended in one year in improving the treatment of 14 cases of fracture.

We all realize that there is very considerable scope for improvement in our treatment of fractures. Most of us will acknowledge that if we are given paper and a pencil and the pocket of the British taxpayer, that so many in the present day seem to imagine is bottomless, to finance

our schemes, we could produce in half an hour an excellent plan on paper wherein there was created something similar to a field ambulance at every coal-face and a casualty clearing station at every pithead. But, fortunately, we will not be called upon to do this, and something more economical and more efficient, at least as the Briton works, will have to be produced.

THE PART OF THE GENERAL PRACTITIONER.

I think it is of vital importance, when any scheme of medical reform is being discussed and thought out, that the cardinal underlying fact should always be borne in mind that it must be based on the general practitioner of medicine, who has the care of the health of the industrial army. All such schemes should be so thought out that, when completed, they come to the general practitioner, not to take from him the cases he is at present treating successfully and economically, but preferably he should be approached and asked what he requires to do that work more efficiently, more rapidly, and more successfully. The care of the recent accident and the arrangement for its transport must always be his sphere of duty. The equipment necessary to carry that out can, however, be centralized for him and distributed as he advises.

The serious case of fracture will always require prolonged institutional treatment, and the question is who is best able to carry that out. In the issue of the BRITISH MEDICAL JOURNAL of November 20th, 1920, you will read a most interesting article by Sir Robert Jones on orthopaedic surgery in relation to hospital training. He advocates that all fractures, whether recent or old-standing, ununited or malunited, shall be given over to the care of a special orthopaedic surgeon, who shall have a fully equipped department to deal with them.

In certain teaching hospitals I think this is a sound proposal, for these departments would set a standard for all and provide the necessary post-graduate training school for a wide area. For the provincial smaller hospital, however, this scheme appears to me not to be possible; but I consider that it would be an experiment well worthy of being tried to hand over all cases of fractures admitted to such an institution to the care of a member of the staff especially appointed for the purpose. The ideal man for such a post would be a local general practitioner, not too busy, and with an instinctive love for hospital practice. If I had to select him I would choose one whose inclinations were not for work in the operating theatre. I would almost go the length of prohibiting him from doing general surgical operative work. He will find the care of these cases a fascinating study. They will require a daily visit and frequently a call again in the evening. To assist him he will require a whole-time nurse trained in the simple elements of massage. It is absurd and unsatisfactory to expect him to do this work gratuitously or on a charitable basis, and he, of course, would receive payment for his services. The source of this revenue I cannot do more than suggest, but it seems to me that, in the light of the figures I have already given, if the case for efficiency in the treatment of such cases is laid before the master and men concerned, they would not hesitate to meet such an expenditure. The financial saving, if nothing more, it would effect would be immense. Certainly it would well justify at least a five years' trial.

The problem of the fracture case that is discharged from hospital and continues to drag on, showing little improvement, is one of great difficulty, but a suggestion as regards its solution is contained in the BRITISH MEDICAL JOURNAL of September 18th, 1920, in an article by Dr. T. Lister Llewellyn on a physical therapeutic centre, and I am sure it should not be difficult to discover. Such a scheme is voluntary in its features and British in most of its characteristics, and consequently offers, in my opinion, the greatest prospects of success.

On February 8th the 346th anniversary of Leyden University was celebrated by an address delivered by the rector magnificus, Professor R. van Calcar, on the development and significance of modern bacteriology.

At a recent meeting of the Vienna Urological Society, the president, Dr. Zuckerkandl, delivered a eulogium on the late Professor Guyon of Paris, all the members standing up in token of respect.

An Address ON INTERNATIONAL ORGANIZATION AND PUBLIC HEALTH.*

BY
G. S. BUCHANAN, C.B., M.D.,

SENIOR MEDICAL OFFICER, MINISTRY OF HEALTH; BRITISH
DELEGATE, LEAGUE OF NATIONS HEALTH CONFERENCE.

THE invitation of your President gives me the opportunity of drawing the attention of the Society to some recent international arrangements for the promotion of public health, and in particular I have thought it would be of interest to say a few words about the International Health Organization which will shortly come into being, as a result of a series of detailed resolutions which were passed by the Assembly of the League of Nations at Geneva in December. With the project envisaged by these resolutions I have personally been somewhat closely associated, as it was my privilege to be nominated by the Ministry of Health, on the recommendation of the chief medical officer, to be the technical adviser on this subject to the British delegation, and, what in this connexion was perhaps more important, to take part in the original international discussions which were initiated by Dr. Addison more than a year ago, when it became necessary to examine the position in regard to international health matters which had been created by the treaty of Versailles. It will be remembered that by the Covenant of the League of Nations, which forms an integral part of that treaty, the members of the League undertake to take steps in matters of international concern for the prevention and control of disease. The League is also empowered to take over the direction of international bureaux established by general treaties, among which is included the existing Office International d'Hygiène Publique, which was established by the Convention of Rome, 1907.

These provisions undoubtedly form something of a landmark in public health history, by giving formal expression to the importance which health questions now assume in the practical affairs of the government of the nations of the world. They show, internationally, the effect of the same movements which in this country led to the central amalgamation of health services and the creation of a Minister of Health; which in France also have since led to the splitting off of public health administration from the other departmental matters which were overshadowing it at the Ministry of the Interior; which have resulted in the Ministries of Health which have been established in the new countries of Central Europe; and which have brought about also the remodelling and strengthening of central public health services which we are now witnessing in the United States and in our own Dominions. The Covenant wisely recognized that as nations thus increase and strengthen their internal health government, new points of contact, need for common action, and even risks of political differences must arise internationally. It was necessary that a league, designed to secure comity among nations and to prevent or resolve disputes, should bring public health questions within its range of activities.

The practical sanitarian, accustomed to look with small enthusiasm on the elaboration of schemes which appear far-reaching only on paper, and with that mistrust of long views which is so useful in the pursuit of our calling, is perhaps likely to exhibit only a mild interest in the fact that the League of Nations, whose own future in many directions is uncertain, has taken to itself a wide outlook over technical matters—economics, finance, international transit, world conditions of labour, and the like—and has added public health to them. It is for him of greater interest to take the short view, and to ask first whether, as a practical matter, international official action can contribute anything worth having at the present time to public health that cannot be obtained as easily without it, and then to inquire how, through the League of Nations or otherwise, it is proposed that this action should be taken. The manner of doing things, as he knows well, is often at least as important as the matter of them.

To answer this question, it may be useful to begin, and perhaps rather in a wholesale way, by a process of elimination. It must be remembered that the League of Nations represents associated Governments, and its activities depend, first and last, on the views and action of Governments—in other words, it is an official machinery if it is anything. For international co-operation in health questions that do not require official or Government intervention and support a League of Nations machinery would offer little advantage. Accepting this, we can at once exclude from the question before us much that can in a general sense be termed international medical work. All medical science, in a sense, is international; it is as cosmopolitan as music. In medicine, least of all, do we want to ask, when we hear news of progress, whether or not it is "official." Jenner, Pasteur, Metchnikoff, Ehrlich—it is the man's work that leaps to the mind with names such as these, not their nationality. We do not need to set up an international bureau to tell us in all the official languages of discoveries and new knowledge given us by workers all over the world. Have we not enough—even more than enough—of abstracts and summaries and translations? There are special cases, to which I will refer shortly, where we can only get the information we require for public health work through Governments, but all will agree that our own journals, not forgetting the *Medical Science Abstracts and Reviews* of the Medical Research Council, which give them freely and in one tongue, amply suffice for all ordinary needs, while we have also all our medical societies—always on the look-out for information from other countries—and our international medical and sanitary congresses, which are all the better for their voluntary character and independence.

So also with research. At the assembly at Geneva much attention was given to an attractive proposal by the Argentine delegates that the League of Nations should promote medical research on a large scale by establishing and financing a large central research institution, and should take active part in the establishment of health laboratories all over the world for the investigation and prevention of disease. The project, had it been pressed and accepted in committee, would probably have been wrecked on the financial rocks; the budget and commitments of the League and its proposed technical organizations were being closely scrutinized. But it was at least debatable whether on its merits it would have been right to press it. Someone once proposed to give a great mansion and grounds for habitation by poets, where their products could be turned out under ideal conditions of comfort and in contact with other poetic minds. The true medical research worker would probably be as horrified at the prospect as the poet. Without shutting the door to future functions of an official international health office as a clearing house for certain kinds of research work—a matter obviously to be considered—it cannot be maintained that nations wishing to progress in medical science would be doing their best by putting their men and money into any international forcing house for research. Both would be better employed at home. Moreover, the days of private support to public medicine are happily not over. The Rockefeller Foundation, with its world-wide humanitarian scope, gives us an example of a magnificent form of internationalism all the more effective by its freedom from official control.

So again with the great humanitarian institutions. The benevolent in all civilized countries combined in the interests of international public health. The various Red Cross organizations, now so much strengthened in authority and funds by the war, have united to form a common organization—the League of Red Cross Societies—which is to work for health in time of peace, with the special function of educating and helping backward or poverty-stricken countries. These Red Cross activities received special recognition in the Covenant of the League of Nations, which requires the signatory countries to encourage them. I do not propose here to formulate the lines of demarcation which should be followed between this important voluntary body and an official health organization of the League of Nations, especially as the matter has been recently and fully discussed by Sir George Newman in his first annual report to the Ministry of Health. The various conferences on the subject have always led to the same conclusion—namely, that in practice the line should be easily drawn (the more so as the League of Red Cross Societies is itself

*Read to the Society of Medical Officers of Health on February 18th, 1921.

established in Geneva); that not only should there be no reason for rivalry, but each should be strengthened by the other. It is the fact, I believe, that the League of Red Cross Societies has already found itself hampered by the absence of a health section at the League of Nations, and it is obvious that the latter, when established, will be much advantaged by what has already been accomplished and prepared by the Red Cross organization. The situation, in fact, is one which is familiar to public health officers in every administrative area where voluntary work and expenditure of voluntary funds on health matters go on side by side with official work; when ordinary tact and prudence is exercised harmony and mutual benefit is secured.

WORK FOR THE INTERNATIONAL ORGANIZATION.

If any further fears are entertained that those who have been concerned with this question have been carried away by unreasoning international idealism, or have bureaucratic designs to capture public medicine at large by some new international machinery, they will, I think, be sufficiently dispelled by a study of the objects which the proposed organization is in fact required to fulfil. These objects are stated as follows in the resolutions of the Assembly; it will be seen that their terms are carefully guarded.

OBJECTS OF THE INTERNATIONAL HEALTH ORGANIZATION.

- (a) To advise the League of Nations in matters affecting health.
- (b) To bring administrative health authorities in different countries into closer relationship with each other.
- (c) To organize means of more rapid interchange of information on matters where immediate precautions against disease may be required (for example, epidemics), and to simplify methods for acting rapidly on such information where it affects more than one country.
- (d) To furnish a ready organization for securing or revising necessary international agreements for administrative action in matters of health, and more particularly for examining those subjects which it is proposed to bring before the Standing and General Committees, with a view to International Conventions.
- (e) In regard to measures for the protection of the worker against sickness, disease, and injury arising out of his employment which fall within the province of the International Labour Organization, the International Health Organization will co-operate with and assist the International Labour Organization, it being understood that the International Labour Organization will on its side act in consultation with the International Health Organization in regard to all health matters.
- (f) To confer and co-operate with international Red Cross societies and other similar societies under Article 25 of the Covenant.
- (g) To advise, when requested, other voluntary organizations in health matters of international concern.
- (h) To organize missions in connexion with matters of health at the request of the League of Nations, and with the concurrence of the countries affected, within the limits provided by subparagraph (a), or by the International Convention of Rome (1907).

The way is now clearer to continue with the practical question which I have assumed to be put. The objects of the organization have been settled and defined in the general terms which I have just given. Representatives of the public health departments of the civilized countries of the world will be collected together to pursue them. What is ready to their hand to begin upon?

The material is really abundant and important, none the less important, perhaps, because the subjects concerned are somewhat technical, and unlikely to make much appeal to popular imagination. We have first a number of health questions connected with frontiers, both sea and land. The measures taken in regard to ships coming from infected ports have in this country a long history, beginning with the now obsolete Quarantine Acts, going on to the International Sanitary Convention of 1903, with which our present practice conforms, and ending with the most recent International Sanitary Convention, that of 1912, the ratification of which was completed only a few months ago. One of the most creditable contributions of this country to the public health of the world resulted from the appreciation which was given in England at a very early stage to the fundamental principles which should govern the action taken by port authorities to prevent the introduction of diseases like cholera and plague, so as to combine a maximum of efficiency with a minimum of interference with traffic and commerce. The international

adoption of these principles, though secured by international agreements, has, however, not seldom stopped at the signature of these agreements. Some countries have regarded sanitary conventions as merely giving minimum requirements, and in practice have superseded them by laws and regulations greatly in excess of the principles of the agreements to which they are signatory. Other countries, including certain of the British colonies, have stayed out of the conventions and retained old-fashioned quarantine laws. All these conventions depend in large measure on a system of formal notification to other countries of the first occurrence of plague or cholera in an affected country, but their requirement has often been defeated by the burden of its own formality. Under the conventions the health department of one country does not notify the health department of another, but the information proceeds through diplomatic channels and foreign offices, for which, naturally enough, any report of plague or cholera carries with it visions of disaster, restrictions, reprisals, and other fantasies which attend the unknown, and thus leads, if not to suppression of facts, at least to delay and to studied ambiguity in their presentation which defeats the object of the notification. And perhaps the greatest difficulty with these conventions—the observance of which is of such great importance to commerce as well as to health—is their want of elasticity. The Convention of 1912, drawn up after long conferences and discussions, was ratified only last year. Though in many ways a satisfactory code, and in advance of that of 1903, it is already in several respects out of date—in regard to plague precautions on ships it still treats human plague infection, and not rat plague infection, as the primary consideration; in regard to cholera, it gives no sufficient guide about the carrier; in regard to yellow fever, its requirements do not satisfy, and are not practised by, any of the countries in the yellow fever zone, and they are considered insufficient by India, which is now apprehensive of the introduction of this disease.

Meanwhile, there is an insistent demand, not only from our own administration, but from that of many other nations, for the establishment of international rules which should govern the handling of other infections, such as small-pox and typhus, not dealt with in the present conventions. These are of daily importance, particularly in connexion with the migrations which are beginning, and likely to be continued, from the epidemic-stricken regions of Eastern Europe. The demand for revision here extends to the case of land frontiers, which hitherto have received scant consideration in international conventions. The division of large parts of Europe into new States, the probability that for many years to come small-pox, typhus, cholera, and other acute epidemics may progress westward through the Continent, and particularly the unhappy experience already gained on the borders of Poland and Soviet Russia, make it essential on land frontiers that, on the one hand, strict measures should be taken for observation, detention, disinfection and the like, applicable to persons of all nationalities; and, on the other hand, that these measures, like those for shipping, should be so contrived as to produce the minimum of interference and annoyance in international traffic and commerce.

Now, in present circumstances it is difficult for any busy public health officer to contemplate without dismay the prospect afforded by a new and protracted official international conference to recast and reconsider all these questions.

Many new States will for the first time come into these deliberations; they cover a larger ground than before; and when a solution is ultimately arrived at, there is a prospect that it can only be made effective by a repetition of the diplomatic procedure which delayed us for eight years after 1912, that the resulting document might once again be out of date by the time it is ratified, and that it would, after all, leave us as uncertain as before of the extent to which the Convention, when completed, was observed in practice by the signatory countries.

An official central health bureau, with international authority and adequate machinery, affords the most hopeful way out. It has already been proposed that the next International Sanitary Convention should be framed on broader and simpler lines, leaving details to be filled in by schedules and supplementary agreements. This is feasible if a standing expert authority has the duty of making adjustments as occasion requires to meet advances

in knowledge and changes in the epidemic situation. In an International Health Organization on which all the central health departments of the chief maritime States are represented there should be no difficulty in designating the right men for this purpose, and in securing international approval of necessary amendments without long delays and needless formalities. Such an organization, moreover, could do much to secure that accurate information is obtained regarding the measures taken in each country to give effect to the agreements.

The Geneva resolutions, besides providing for this central body, lay down a new method for the conclusion of conventions on health matters which, it may be hoped, will remove some of the obstacles met with hitherto. The efficacy of this method has still to be tested, but in any case the main cause of past delays—the fact that it has been nobody's business to see to progress—should now be removed.

Another matter requiring attention at the present time is the collection of intelligence regarding the progress and prevalence of principal epidemic diseases. At the Ministry of Health we find this essential not only for our own sanitary administration, but also to meet, as we desire to do, the strongly expressed wishes of our self-governing Dominions for such systematic intelligence. Port medical officers of health who receive from the Ministry the weekly statements of epidemic diseases abroad, which have lately been much expanded and improved through the energy of my colleague Colonel S. P. James, will realize the duplications of labour which result from the present system—indeed, its absurdity, when it is remembered that other countries, like the United States, are laboriously and independently following the same method. At present we obtain a large amount of our information about epidemics by the co-operation of our Foreign Office and through the zeal of British consuls abroad. In existing conditions this is the only way, and is most helpful. But, after all, the consul, himself a layman, has to approach a foreign lay municipality for his facts, and at best can obtain them only for a limited area of the country. Other consuls at the same place are going through the same system of inquiry and cabling to their Governments. For some countries, China, for instance, no efficient substitute for consular information can be suggested. But for many nations it ought to be practicable to replace messages from British representatives in a few centres by a single communication sent to the Ministry of Health by the corresponding department of the foreign country. We are already in England able to give such information either to other countries or to a central office. The practicability of the establishment of a central epidemic intelligence centre in connexion with the new International Health Organization needs to be studied in detail and as soon as possible. It would hasten more than any other measure the codification of epidemic intelligence in countries like France which have not yet developed notification as we know it over here. Given the necessary communications from the periphery, a central transmitting station such as the League of Nations is bound to possess, and the condensing resources of a code, it should not be difficult in a few words to signify each week to all the countries the main facts of each of the principal epidemics which require to be watched. Much less useful matter is daily transmitted all over the world by wireless. The expense should not be great, and would be saved in other directions by every country concerned.

The hygiene of ships, so far as it affects that deserving but often hygienically neglected section of the population termed merchant seamen, is receiving attention on the international side from the International Labour Office, and is being brought into great prominence by seamen's labour organizations all over the world. Its settlement requires international action in which the best and most recent public health knowledge should be incorporated. The Geneva resolutions establishing the International Health Organization have now provided a means by which competent sanitarians can take their proper part in the international regulation of matters like ship ventilation, the construction of crews' quarters, their rations, facilities for cleansing, and the like. The subject bristles with difficulties, but also with great opportunities, and I may express the hope that when proposals on this matter are taking concrete form, the British delegates may have the

advantage of assistance from those medical officers of health of port sanitary authorities who have specially studied the hygiene of ships' crews.

Let me refer also to another international measure affecting merchant seamen—their treatment for venereal disease at seaports. This ground has been explored officially by the Ministry of Health, and unofficially by the National Council for Combating Venereal Diseases, and we are convinced that international agreement is both desirable and practicable to ensure that at any large seaport the sailor has access to modern methods of treatment, without charge or disability to himself, without reference to his nationality, and, if I may express a personal view, without cost or prejudice to the shipowner. This treatment should include in-patient treatment where necessary, and a standard form of record of his condition and treatment—forms of record really may have their uses—which he can take with him to the next port.

Nothing approaching this system at present exists, but little consideration is necessary to realize the gain which might accrue from such an international undertaking. The practical difficulty hitherto has been that no one nation has been in position to press the matter strongly on other nations and remove the minor obstacles, still less to secure that the goodwill and assent of other countries, when obtained, is translated into appropriate action.

I may refer to two or three other health questions which seem ripe for international agreement, or study with a view to agreement, and should where necessary be taken up in consultation with the International Labour Office in the interest of the workers. One is anthrax, where at least two things are required: First, the general adoption of a system officially recognizing that raw hides and wool have been disinfected by an approved process at the place of their collection or the port of dispatch. This system, which would produce a great saving and greater efficiency, has been shown to be practicable by the work of Dr. Legge, Dr. Euriich, and others in this country, and the minute attention given to the whole question by the Anthrax Committee and the Home Office. Secondly, there is real need for an understanding about the future of the important Japanese export trade in shaving brushes. The British Government has been obliged, by the demonstrated danger of these brushes, to prohibit their importation altogether. It is undesirable that we should have been forced to this procedure, especially as other countries have not taken corresponding action. The real remedy seems to lie in action in Japan to secure that the hair, usually imported from China, is efficiently cleansed and disinfected before it is made up, under the supervision of Japanese bacteriologists, in whom all the world can have confidence, officially arranged and guaranteed by the Japanese Government.

Then again, to revert to a subject which affects port sanitary authorities and shipping, there is the subject of periodic destruction of rats on ships. There is no reason why a ship should not be overhauled to remove its rats every six months as a routine just as necessary as its repainting, or the overhaul of its boilers. Such a requirement, which would be greatly in the interests of shipowners, as well as of health, could only be effected by international agreement, coupled with a system of intelligence at the central offices regarding the action to give effect to the requirements of that agreement.

There can be no doubt that the work of medical statisticians is greatly hampered by unnecessary differences which at present exist in methods of certifying and of recording deaths. I may draw attention in this connexion to a useful article on death certification contributed by Professor Glaister to the last number of the *Journal of Comparative Legislation*. When one remembers that the vital statistics of Switzerland, for example, are obtained by a system of confidential certification in which the medical cause of death is not stated to friends and relatives, one realizes how large a discrepancy there may be in the comparison of the vital statistics of that country with others in respect, let us say, of alcoholism or syphilis. Then, again, the use by the certifying doctor of "primary" and "secondary" causes of death is a matter in which there are divergencies so wide as to make vital statistics which are seemingly comparable really incompatible in actual fact. Even as between England and Scotland there are a few differences of this kind: a death which is certified as due primarily to

influenza and secondarily to pneumonia will in England be ascribed to influenza, and in Scotland to pneumonia. There must, of course, be substantial differences between countries in regard to the reliability of their death certificates and vital statistics, even between those which are most highly civilized; but, at the same time, a great many points of difference have only to be pointed out and discussed in order to be removed, with great advantage to comparative work. Some effective progress has already been made in this matter on the question of tabulation of causes of death under the headings of the International List, which is revised every ten years. The conference last year at Paris, which completed the most recent decennial revision, was at once an example of the praiseworthy desire of statisticians and registrars to obtain international accord in their "long" and "short" lists of causes of death, and a demonstration of the ineffectiveness of the arrangements which at present exist to bring about that accord in a satisfactory and convenient manner. Anyone who experienced, as I did, the difficulties of discussion of a large number of complicated details by fifty delegates of different nations meeting on four consecutive days from early morning to late night, and trying to make progress without agreed rules of procedure, agenda, drafts, copyists, shorthand writers or interpreters, would not need to be convinced of the practical advantage of transferring such work to a centre where all these arrangements for international discussion are automatically and well supplied.

Another important aspect of international official work lies in the direction of combining efforts to deal with exceptional epidemic conditions. This has already been illustrated in connexion with the advance of typhus and cholera from Russia into Eastern Europe. To check that advance, especially by dealing at the frontiers with the large numbers of refugees, prisoners of war, and the like arriving from the East in mass along the principal railway lines, *en route* to all parts of Europe, is a matter which obviously concerns many Governments very vitally, apart altogether from the humanitarian aspect of the question, which may be considered to affect the whole world. A large amount of voluntary aid has been forthcoming or promised to deal with this situation, especially through the Red Cross agencies, but the conditions in Poland and the other border States has been such that it has been impossible for this voluntary action to be made effective without strong official international backing. Moreover, the resources of the charitable public in the United States and elsewhere have been insufficient to secure the necessary preventive measures on a sufficient and systematic scale. In these circumstances, the League of Nations, as is well known, has made an effort to supply the need by appointing a special epidemic commission and obtaining funds for this work from a large number of the Governments represented in the League. Although these funds are not yet adequate for the purpose, they have even now been sufficient to enable a good start to be made in the most difficult and dangerous area, and the Typhus Commission, with general consent, is now able to attach to itself, or direct the use of, the important auxiliary services which the Red Cross bodies are able to bring in.

Occurrences of this kind are not likely to be numerous, as in all ordinary cases an epidemic-stricken country would take its own measures and be unwilling to call for, or to receive, international official help. When they do occur, however, as to-day in Eastern Europe, or as they may arise to-morrow, say, in the case of pneumonic plague in the East, it is evident that the League of Nations can only act effectively and quickly if it has behind it experts who can appreciate the situation and the needs of the case, and are in close touch with their Governments. The absence of a public health organization in the present case has been one of the serious handicaps to the League in the prosecution of its campaign against typhus.

It may be added that if the Treaty of Sèvres is ratified, still more if it is taken as a precedent for other treaties, the League of Nations will assume a very direct responsibility in regard to quarantine. Under that treaty the League will be required to form a special committee to co-ordinate the practice of the different quarantine stations which deal with the Mecca pilgrimage.

METHODS OF ADMINISTRATION.

Leaving these questions of the work before the organization, we may now consider the further practical question how such work is to be effected. It requires that a body of men should be got together at least once or twice a year from a large number of countries who are persons of some weight and authority in the public health work of their respective Governments, and who, if they are not themselves expert in the particular technical question of the moment, will have been able to obtain or to bring the best technical assistance or advice on the subject. If we were on entirely new ground with no experience, it might be difficult to say that this is likely to be practicable. Fortunately, however, we have the necessary experience. Such meetings to a large extent already take place once if not twice a year at the Committee of the Office International d'Hygiène Publique in Paris, which is to form an integral part of the new organization. This Committee is in one important respect wider than any body could be which only represents members of the League of Nations at the present time, as it includes the representative of the United States Public Health Service. The Office International d'Hygiène Publique was established by the Convention of Rome of 1907 with a constitution which enables it, as a consultative body, to deal with most, if not all, of the subjects which I have mentioned above. The value of the past work of the Office International must not be belittled or overlooked. It is hardly as well known in this country as it should be. The Office has been a very bad advertiser, and, as its meeting place and offices are in Paris and its official language is French, it has been regarded here as perhaps too exclusively a Latin institution. The *procès verbaux* of its meetings are formidable official records which are seldom found outside Government offices, and its *Monthly Bulletin*—which is on sale and, incidentally, at the rate of exchange of to-day, represents a higher public health value than any other periodical known to me that is purchasable for 5d.—is largely concerned with official regulations, and its abstracts and epidemic intelligence, though very well done, are apt to be a little out of date.

As regards its conferences, I can only speak personally regarding those held since the Armistice under the able presidency of M. Velghe, the Principal Officer of the Belgian Public Health Service. There can be no question of the great practical value of these meetings, which has been proved especially in connexion with the influenza interchange and collected regarding the influenza pandemic, the present prevalence of encephalitis lethargica, the practical measures adopted to deal with venereal disease in other countries, and other matters. At the recent sessions, moreover, since the question was raised of providing for international health work on a larger scale and with more important machinery and larger funds, the delegates to the Office International have most materially advanced the consideration of a number of the international questions to which I have already alluded, in particular the revision of the Sanitary Conventions and the proposed agreement to deal with venereal disease at seaports. In general it may be said that the delegates are precisely the men who would be selected by their Governments to represent them on any important international health question involving official action. The British Empire representation has recently been a strong one, as we have been fortunate in including representatives who are either leading public health officers in their respective British countries or have recently held such appointments.

All those who have had to consider the way in which the health obligations in the League of Nations Covenant should be met, and the nature of the problems before us, have agreed that continuity should be secured and that the League would benefit by the experience and personnel of the Office International. Moreover, the Covenant has made it impossible for the Office International to develop in any useful direction by continuing an independent existence. This view by general consent and goodwill has now been adopted in the resolutions of the Assembly. The International Health Organization is to be based on the Office International, which will in future have additional representatives from certain countries like Japan, which are members of the League but have not previously sent delegates to the Office. The League of Nations

system of General Assembly, Council, and Secretariat, has, broadly speaking, been followed in the subsequent arrangements. The Committee of the Office International, enlarged as indicated, becomes the equivalent of the General Assembly of all the nations. Under the name of the General Committee of the International Health Organization it will continue to meet in Paris once or twice a year and retain its offices there. Its work will be carried on under its former constitution, with such modifications as may be necessary to fulfil its further duties of advising the League. It will, however, be provided with a standing committee, roughly analogous to the Council of the League, which can meet in the intervals of the general meetings, appoint subcommittees, and arrange for expert inquiries, and it is to have a medical secretary and office at Geneva. The Assembly has allotted some £17,000 to the organization for its first year, and it will continue to receive also the relatively small contributions from the signatory Governments which have hitherto supported the Office International.

It may be noted with satisfaction that the official requirements for the working of the organization laid down by the resolutions of the Assembly are, as international arrangements go, relatively simple. Much latitude has been given to the organization to work out its own procedure as circumstances dictate.

It is true that the system could have been very considerably simplified if we could have envisaged the appointment at Geneva of a superman for international health, possessing a large central office and staff, in position to prosecute inquiries in and demand information from the respective national health offices of the world, and to lay down international rules with which those national offices would comply. But no public health department in any country would be prepared to accept this dictation at the hands of any man, however distinguished. And if they were so prepared, no Government would be disposed to accept such a system. There were, indeed, many indications at Geneva of the intrinsic objection held by the representatives of the constituent nations of the League to any international procedure which suggested servitude to a central bureaucracy.

Common action among nations, for purposes such as we are considering, must depend upon the fullest discussion and consideration of the position of each country—even in such technical matters as quarantine laws or death certification or standards of ships' hygiene—and on willing agreement after such discussion. This means a slow rate of progress, of course, but it is necessary, and the originators of the health scheme have recognized it by making the meetings of representatives of all countries—that is, the General Committee which continues the Office International d'Hygiène Publique—the real basis of the organization; the new additions of standing committees and secretariat being the necessary auxiliaries to its efficient work. Any permanent headquarter officers who are appointed will need ability and experience in handling the subjects for inquiry and giving effect to the decision of the international representative body. But these, after all, are qualities exercised every day by medical officers in every important public health service, no more difficult or complicated than managing the health matters of a great municipality. They require good men, but not Napoleons.

CONCLUSION.

It is permissible, I think, to conclude from this short survey that the International Health Organization of the League of Nations will have before it on its formation a number of important practical matters of hygiene which are ripe for concerted Government action, and already call for an organization representing the official public health services of the civilized Governments of the world; that it will start on these subjects with the advantage of continuing the collaboration which has been obtained in the more limited sphere of the Office International d'Hygiène Publique under the Rome Convention of 1907, and of the preliminary work already done by that Office in several of the subjects awaiting settlement; and finally, that the means and funds placed at the disposal of the organization for meetings, inquiries, and draft agreements, promise to be satisfactory for the purpose.

I think this is quite enough to enable us to wish it a good start and every success on an admittedly difficult road, without prophesying for it a future extension in

many other directions which can be suggested, or must even be anticipated if the League of Nations increases its authority and influence, or if, whether through the League of Nations or in any other way, the countries of the world demand in future a much closer degree of international co-operation for objects such as public health. In any event, the outlook for the organization will largely depend on the willingness of the public health services in the different countries to make use of the present opportunity, and the support which these services in so doing receive from their Governments. One satisfactory part of the scheme adopted by the Assembly should be noted. The League of Nations will have its budget control, a certain power of withholding sanction to action proposed by the organization, the right of sanctioning appointments of paid officers, and of receiving reports, but, apart from these, the general working of the organization, the regulation of its internal affairs, and the appointment of staff is left entirely to the organization itself—in other words, to the public health men themselves.

Here is the opportunity of the public health officers, and it is to be hoped that they will not only be willing to seize it—this may be taken for granted—but will find themselves in position to give necessary time and labour to ensure its success, and be supported in their respective countries by departments which realize that practical international action and agreement is a fundamental part of any good State public health policy. As regards countries within or associated with the British Empire we have every reason to anticipate that this support will be given in the Dominions, India, and Egypt, as well as at home.

As I have said so much about this new organization it is only fitting that I should conclude by reference to a few of those to whom the fact that it has now been established by resolution of the Assembly is mainly due. These preliminary steps have not been achieved without labour. Many of us have worked hard at the matter at the Ministry of Health, and much is due to our French colleagues, M. Brisac and Dr. Bernard; to Dr. Lutrario, the chief of the Public Health Service in Italy; to Dr. Hugh Cumming, now head of the United States Public Health Service; to the Japanese representation; and especially to the principal officers of the Secretariat of the League of Nations and of the Office International d'Hygiène Publique, all of whom originally took part in working out the main lines in 1919 at the London Conference under the guidance of Lord Astor. At the Assembly itself the scheme was fortunate in having such able exponents as the Right Hon. G. L. Barnes, M.P., the delegate for Great Britain, and Monsieur Gabriel Hanotaux, for France; their statesmanship and industry piloted it past the not inconsiderable difficulties inherent in the first establishment of technical organizations by the League, and in the official requirement that resolutions of the Assembly can only be obtained by a unanimous vote of all the nations represented.

A NEW PRINCIPLE IN THE SURGICAL TREATMENT OF "CONGENITAL CLEFT PALATE," AND ITS MECHANICAL COUNTERPART.

BY

H. D. GILLIES, C.B.E., F.R.C.S.,

Surgeon, OUPEN'S HOSPITAL, SIDCUP; Surgeon, DEPARTMENT OF PLASTIC SURGERY, PRINCE OF WALES HOSPITAL, TOTENHAM, AND

W. KELSEY FRV, M.C., M.R.C.S., L.D.S.,

DIRECTOR OF THE DENTAL PROSTHETIC LABORATORY, GUY'S HOSPITAL.

I.—THE PRINCIPLE.

By H. D. GILLIES.

I BELIEVE that the revolutionary principle outlined below, if adopted by surgeons handling cleft palates, will lead to a very great improvement in the results of these difficult cases. My very limited experience does not allow me to make any sweeping statement of fact. I hope, however, that the correctness of this principle will so appeal to the surgeon that he will seldom attempt to repair the hard palate, and never before the eruption of the permanent teeth.

The ideals to be aimed at are: Perfect speech; perfect mastication; normal nasal respiratory function; and, in as

far as a displaced maxilla causes deformity, a normal bony contour. The success of a palate operation is often gauged merely by the completeness of the surgical closure. This should not be so, as it is hoped to show that successful closure of a wide cleft by any of the present-day operations is incompatible with the full attainment of the above ideals.

Speech.

The factors producing perfect speech are a united soft palate, with its musculature intact, and lying in such a position that it can be raised and pressed against the pharyngeal wall, and can control the amount of air for the post nasal space, together

with a shutting off of the oro-nasal communication left by the congenital defect of the hard palate. Add to this, but of less importance, a set of teeth in a normal position. How are these factors reproduced in the average result of the three main types of operation at present in vogue—the Brophy, the Lane, and the Langenbeck?

The "Brophy" approximation of the maxilla is usually combined with the "Langenbeck" suture of the soft parts, and the more the cleft is reduced by bony approximation the less is the soft palate displaced forward when sutured, and therefore the better is its subsequent action as to air control. In most operators' hands, however, there is usually some destruction of tooth buds and some permanent displacement inwards of the alveolar arches, and the wider the cleft the greater are these defects of mastication, and to a certain extent of speech and breathing. With this type the best soft palate result is likely to be accompanied by a poor hard palate result, as judged, not by the closure, but by the articulation of the permanent teeth.

The "Lane" type theoretically should produce a good soft palate in addition to a hard palate closure; but too frequently the soft palate is much scarred and tight, and, in addition, lies so far forward in the buccal pharynx that its remaining utility as a speech controller is largely discounted. The hard palate defects of the flap operation are discussed later.

The "Langenbeck" type of approximation frequently results in a good movable soft palate, and a surgical closure of the hard palate; but the wider the cleft the shorter must be the palate, hard and soft, as measured from alveolus to uvula, consequently the new soft palate is in a position anterior to the normal, and by as much as the soft palate is drawn forward its speech control is in proportion adversely affected.

Many of the above defects are frequently counteracted by good orthodontia, massage of the soft palate, speech training, and the natural ability of the patient to overcome obstacles. The majority are not, and the skilled service necessary to these secondary defects is not always available or, if available, effective.

Mastication.

If Brophy were right in his premiss that the width of the cleft equals the spread of the maxillae, then his principle would be correct, but he is not. (See Blakeway, *Lancet*, March 6th and 12th, 1915.) Moreover it is doubtful whether Blakeway's measurements form a true index to the position of the maxilla in regard to the mandible, as a very great percentage, if not all cases of unoperated palates, have perfect occlusion (and so mastication) of all

the permanent teeth except those involved in the alveolar part of the cleft, which in both operated and non-operated cases are displaced. In addition to the tooth buds that may suffer from "Brophy's" wires, the upper teeth are inclined to be displaced inwards by the operation, as performed in this country.

The "Lane" flap taken from the alveolar region most frequently interferes with the normal eruption of the teeth, and in addition the fibrous tissue in the united palate and in the scarred area of the alveolus causes a chronic and contractile force between the two halves of the maxilla, and produces an eruption of teeth whose bite lies well inside

those of the mandible—that is, a narrowing of the maxillary arch as compared with the mandibular.

The same malocclusion frequently results also from the Langenbeck type of approximation, where the same contractile force is in play, to a greater or less extent according to the success of the closure and to the width of the cleft. The earlier the hard palate is closed by the Lane or the Langenbeck type of operation, the greater chance has this contractile factor in producing malocclusion. In any case of malocclusion

of the teeth in an operated palate such a serious defect may definitely be assigned to the result of the operation, and would not have occurred had the hard palate been left alone.

Nasal Respiration.

In all three types there is thus a tendency to an undue approximation of the maxillae. Hence a narrowing of the nasal passages. I think that much of the nasal trouble attributed to palate cases is due to the operation of closing the hard palate, and not to the oro-nasal communication. A secondary factor enters this part of the problem, however, in the deformity of the alae and tip of nose so often present before and after the repair of the accompanying hare-lip. A scarred, immobile, and forwardly displaced soft palate must also have its deleterious effects on the upper respiratory mucous membrane. I have also observed in many operated cases a dragging upwards and forwards of the pillars of the fauces and of the important tonsil lying between them. It is not inconceivable that much throat and nose trouble lies at the door of this displaced tonsil, deprived of its normal muscular massage, and so, after the manner of "the house that Jack built," at the door of the surgeon who closed the palate.

Appearance.

Hare-lip deformity not being under consideration, being under surgical closure

it remains to discuss the effects of the surgical closure of the hard palate on the general facial appearance. Whenever from any of the above causes there is a post-operative and undue approximation of the maxillae, the lip, tire and other qualities, is liable to be flat, and on whatever its other qualities, is liable to be flat, and on a plane posterior to normal. The frontal processes of the maxillae move inwards, and usually backwards, with the displaced bones, and consequently the whole of the lower part of the nose is situated on a plane further back than normal, and gives an appearance characteristically represented in Fig. 1, A and B—an actual case. The cure for this deformity of contour is to be found in the epithelial inlay or buccal skin graft, similar to that described in the writer's book on *Plastic Surgery* (see Fig. 2).

FIG. 1.—Facial appearance of patient following surgical closure of the hard palate. The backward displacement of the lower part of the nose is shown in B.

FIG. 2.—Facial appearance following epithelial inlay or buccal skin graft for deformity shown in Fig. 1.

Other Surgical Methods.

The hard palate may be surgically closed by introducing, between the two halves of the maxilla, sufficient tissue from a distance to make good the defect; the reader is referred to various neck and other flaps, including the writer's "tubed pedicle," introduced into the buccal cavity, none of which are recommended; and to the introduction into the defect of turbinates and septum grafts, of use in the small defects of the war. It is of significance that Mr. Brophy has on two occasions urged the writer to develop the tubed pedicle method to fill palate defects in lieu of his bone approximating operation.

Treatment Recommended.

The writer and his colleague, Mr. Fry, consider that closure by means of an efficient dental plate is by far the most simple and efficient mode of treatment; it gives least trouble and provides all that is required of a hard palate as regards feeding, speaking, and breathing, and is applicable in some form or other from earliest infancy. Its very nature prevents any interference with the maxillary growth and eruption of teeth, and saves part of an operation whose mortality is not inconsiderable.

Having decided to make good the hard palate defect by a removable prosthesis, the writer suggests that the two halves of the soft palate be united in as far back a position as is possible. It is not presumed to put forward any fixed operative technique on such flimsy grounds, but the two halves of the soft palate have been separated from the

and caused him to evolve the principles enumerated above, which he hopes may alleviate many of the troubles associated with this condition.

Summary.

All unoperated hard palates have normal occlusion of the non-involved teeth.

Nearly all operated hard palates have abnormal occlusion of the non-involved teeth.

Nearly all operated palates have nasal intonation to speech and narrowed features and nasal passages.

Most unoperated adult cases have enjoyed good health.

Most palate cases require a dental plate, whether operated or not.

Recommendations.—(1) Suture soft palate as far back as possible in the pharynx by detachment from hard, making the hard palate defect greater; (2) fill the hard palate defect by appliance from earliest infancy, even at the bottle or breast stage.

Time for Operation.—Lip, early. Palate, before speech development or later.

II.—THE PROSTHETIC TREATMENT.

By W. KELSEY FRY.

The prosthetic advantages of this combined surgical and mechanical treatment for congenital cleft palates are, first, the ease with which restorations of the hard palate can be performed by prosthetic means as compared with the difficulty with which the prosthetist is confronted in the case of the soft palate; and, secondly, the absence of distortion of the dental arch, with resulting loss of masticatory function, which is unfortunately only too frequent

FIG. 3.—Combined surgical and dental treatment of cleft palate. A. Congenital cleft of hard and soft palate. B. Approximation and lengthening of soft palate, which is completely separated from the hard palate. C. Apparatus for the application of skin graft to the raw anterior edge of palate. D. Apparatus by Mr. Fry for stretching soft palate after healing. E. Final result: Hard palate filled with dental appliance, a long movable soft palate which can approximate to pharyngeal wall and give good speech. (Diagrams by S. Hornswick.)

hard and sutured together after producing two raw edges of apposition. This manoeuvre leaves a larger hard palate defect than prior to operation, and to prevent the raw anterior edge of the newly-made soft palate scarring over and so contracting forward, two methods have been practised—one to take a small flap of muco-periosteum from the hard palate leaving it attached to the soft, and wrap it over the raw area; the other to overlay a skin graft (Thiersch), held in position by an apparatus (Fry, Fig. 3). The latter is more applicable to those cases in which the musculo-mucous-membranous remains of a previously and poorly operated palate have been deliberately detached from a surgically closed hard palate, and made to lie in juxtaposition to the pharyngeal wall. The gap between the hard and soft palate is more efficiently filled by the dental prosthetist than is the usual posterior defect of the soft palate by means of an artificial velum; and the muscular and movable portion of the soft palate works with much greater efficiency as regards speech and deglutition in its new position. The congenital type operation results in a muscular movable soft palate sufficiently near the pharyngeal wall to control air and food, having its palatal aponeurosis represented by the posterior border of the dental appliance, and in a hard palate absolutely closed by the rest of the dental plate. The principle of the treatment of the displaced pre maxilla in double hare-lip cases is one outside the scope of the present article.

If there be any merit in the above principle, the writer wishes to place on record his gratitude for the lessons in facial contour he learnt from Professor H. Tonks of the Slade Art School, and one time war colleague; and especially to Mr. Kelsey Fry for his tactful handling of an enthusiastic surgeon who first wanted to close all traumatic hard palate defects by plastic operations, and later learnt that surgical success was less efficient and far more difficult to come by than the dental closure. This set the writer thinking in regard to congenital palates,

in cases in which the hard palate has been restored by surgical means.

The aims of dental treatment for these cases may be considered under the following four headings:

1. To aid feeding until such time as the surgical operation is thought advisable.

2. To construct an appliance to hold the epithelial inlay in position at the time of operation.

3. To construct an appliance to maintain the surgically restored soft palate in its correct position and, if necessary, to stretch it in a backward direction so as to enable it to make contact with the posterior wall of the pharynx.

4. To construct a permanent prosthetic appliance to restore the loss of the hard palate and, if necessary, the anterior portion of the soft palate.

1. *To Aid Feeding until Time of Operation.*—When the cleft only involves the soft palate and a small portion of the hard palate, it is only necessary, in order to aid the infant in feeding, to use a specially constructed feeding bottle, by which the liquid is projected into the mouth by means of hand pressure. If the cleft is of a more extensive character, it becomes necessary to construct and fit an obturator on to the teat of the bottle, which will thus prevent food being regurgitated through the nose.

2. *To Construct an Appliance to Hold the Epithelial Inlay in Position.*—Various types of appliances may be used for this purpose, depending on the nature of the individual case and on the presence or non-presence of teeth. The apparatus should be constructed before the operation and should be easily removable. It is also essential that it should be easily adjustable, as it is impossible to locate before the operation the exact position of the anterior edge of the soft palate requiring the skin graft. Fig. 3c shows a general type of appliance which may be used for this purpose.

3. *To Construct an Appliance to Maintain the Restored Soft Palate in Position.*—When it is only necessary to maintain the soft palate in its new position an appliance

should be constructed which will accurately fit the posterior part of the remaining perforation of the palate and thus prevent it being drawn forwards by any resulting scar tissue. It is essential that this appliance should be constructed as far as possible before the operation, as it is necessary that it should be inserted immediately after the appliance holding the skin graft in position has been removed. In cases where it is necessary to stretch the new soft palate in a backward direction advantage is taken of the fact that the combined action of the muscles of the soft palate is in a backward and upward direction. A prosthetic appliance is constructed which will cause gradual pressure to be made upon the anterior portion of the new palate, thus stretching the soft tissues uniting the hard palate to the soft palate, and allowing the muscles to carry the soft palate as a whole in a backward and upward direction. The appliance should be continued in use until the soft palate is able to make contact with the posterior wall of the pharynx when in contraction; as this state is essential for perfect function of speech. - Fig. 3, v, shows the main features of a type of appliance which may be used for this purpose, the details of which vary according to the age of the patient and the number of teeth present.

4. To Construct a Permanent Prosthetic Appliance to Restore the Loss of the Hard Palate.—The permanent appliance merely consists of a dental plate which covers over the remaining perforation of the hard palate, except at its posterior border, where it should penetrate slightly into the cavity, thus making sure contact between the soft palate and the prosthetic hard palate, and at the same time preventing contraction of the soft palate. When it is necessary to restore by prosthetic means the anterior portion of the soft palate, this should be done by means of velum rubber, otherwise the whole appliance can be made in hard rubber or a combination of gold and hard rubber.

From the above brief description it will be noted that the permanent appliance necessary in this combined surgical and prosthetic treatment is of very simple construction and of a permanent nature, thus obviating continual dental treatment in after-life.

THE TREATMENT OF SPRUE BY MASSIVE DOSES OF SODIUM BICARBONATE.

ALDO CASTELLANI, C.M.G., M.D., M.R.C.P.,
PHYSICIAN TO THE MINISTRY OF PENSIONS TROPICAL HOSPITAL;
LECTURER AT THE LONDON SCHOOL OF TROPICAL MEDICINE.

In carrying out, some time ago, certain researches on sprue, I noticed that to render strongly alkaline the urine of patients suffering from this malady it was necessary in most cases to give sodium bicarbonate in much larger doses and for much longer periods than in normal individuals or patients suffering from certain other diseases; the alkali tolerance was therefore increased. During this investigation I noticed that the administration of massive doses of bicarbonate, instead of the usual small or moderate doses so often given in the malady, had frequently a most beneficial effect, especially as regards improvement in the intestinal symptoms, and seemed to help greatly the action of the dietetic treatment.

The routine method of treatment I now use in sprue is generally the following: The patient is kept at complete rest in bed and is placed at first on a strict milk diet. The mouth is kept scrupulously clean by using a diluted alum-carbolic mouth-wash.

Glycer. alum	aa	3iv
Glycer. ac. carbol.	ad	3iv
Aq. rosae		

One teaspoonful to a tumbler of water.

And when painful patches on the tongue are present, a cocaine-carbolic mouth-wash will be found useful.

Cocain	gr.v
Ac. carbol.	5j
Glycer. borac.	3vj
Aq. rosae	ad 3iv

Half to one teaspoonful to a tumbler of water.

A mild alkaline tooth paste should be used to brush the teeth with several times daily. Quite a number of private

patients I see come to me toothless; apparently the first advice most of them had received on arriving in Europe was to have all their teeth extracted. I have never seen, in cases of genuine sprue, the course of the disease arrested by such a procedure, and I strongly deprecate it, except in those cases in which the sprue condition of the mouth is complicated by true severe pyorrhoea. If there is history of recent amoebic dysentery—and this is in my experience very often the case—I give at once a course of six or twelve emetine injections.

In addition to these measures, the patient is placed on an intensive alkaline treatment, which is carried out (a) by giving very large doses of sodium bicarbonate by the mouth, and (b) by intravenous injections of a 2 or 4 per cent. bicarbonate solution.

In a number of cases the administration of large doses of bicarbonate by the mouth is sufficient. It is given in drachm doses, 1 drachm three times daily for the first three days, 2 drachms three times daily for eight or ten days, and afterwards 3 drachms or more three times daily for several weeks. No untoward effects are noticed, but not rarely the patient feels and looks somewhat drowsy for a few days. If the drowsiness becomes marked the dose should be decreased. Papain, takadiastase, pancreatin, etc., may be added to the bicarbonate, but the effect of these digestive drugs is not very brilliant in the acute stage of the malady, and I generally omit them altogether during the first weeks of the treatment; later, such preparations, and especially pancreatic extracts as emphasized by Brown, are useful. When the diarrhoea is very severe 5 to 10 grains of salol may be added to the bicarbonate, but powerful astringents should always be avoided. The addition of a little salol to the powders is also useful when the urine becomes too strongly alkaline. In those rare cases in which there is constipation, magnesium carbonate gr. x-xx may be substituted for salol.

The standard formula of the powders is:

Pulv. cinnamom.	gr.53
Pulv. ipecac.	gr.68
Pancreatin, papain, or takadiastase	gr.1ij
Salol	gr.v
Sod. bicarb.	3ij

The powders should be given in half a tumbler of water. The amount of the ingredients should be varied according to the symptoms presented by the patient, as already stated, and some of the drugs (cinnamon, ipecacuanha, pancreatin, salol) may be left out altogether. At times in conjunction with the powders I have found it useful to administer bile salts (sodium taurocholate gr. ij in cachets t.d.).

In certain peculiar cases of sprue characterized by severe asthenia and a distinct hyperpigmentation of the skin, in addition to the bicarbonate treatment, I have given adrenalin with good results.

I have used intravenous injections of sodium bicarbonate so far in six cases, always in combination with the internal administration of large doses of bicarbonate as described above. Ten to twenty ounces of a 2 or 4 per cent. solution of bicarbonate is given slowly every day or every other day until twelve injections have been given; then the patient has a rest, but the intensive alkaline treatment by the mouth is continued. After an interval of one or two weeks another course of injections is given, and a third course may be necessary after a further interval. The intravenous injection should be given preferably by the gravitation method, observing all the precautions commonly used in intravenous therapy. In the sterilization of the solution care should be taken to prevent any excessive formation of the carbonate, and this end is best achieved by taking the precautions suggested by Sellard—namely, the bicarbonate solution should be put in strong narrow-mouthed bottles which are filled almost full in order to reduce the air space to a minimum, tightly-fitting stoppers being used. As an additional precaution, these bottles can be sterilized in an atmosphere of carbon dioxide; this can be easily obtained by raising the autoclave to the boiling temperature, while water at the boiling point is provided at the bottom of the autoclave, and a handful of bicarbonate is thrown into the hot water.

I have used the bicarbonate treatment here described in a large number of cases, and in 11, most of them private patients, I have been able to follow the course closely. My experience has been that sprue cases having this treatment, in addition to the usual dietetic measures, improve more rapidly than patients having only the

dietetic treatment, though of course there are exceptions. It is interesting to note that the intestinal symptoms seem to be much more beneficially influenced than the mouth symptoms.

As regards the mode of action of the intensive bicarbonate treatment, I have very few remarks to offer. At one time I believed that large doses of bicarbonate by decreasing the acidity of the intestinal contents might check the growth of monilia fungi, considered by some authors to be the true cause of the malady, and by Low and myself to be merely the cause of certain symptoms, as, for instance, the floathiness of the stools. If recent hypotheses concerning the etiology of the malady be proved correct, then a different explanation will have to be found. At any rate, there appears to be little doubt that in sprue a certain degree of acidosis is often present, and that an intensive alkaline treatment is indicated.

Conclusion.

The administration in sprue of massive doses of sodium bicarbonate by the mouth and intravenously, in conjunction with the usual dietetic measures, gives satisfactory results in a large number of cases, especially as regards the intestinal symptoms of the malady.

ANGINA PECTORIS WITH AURICULAR FIBRILLATION.

BY

HAMILTON M. SANDISON, M.B., CH.B. Edin.

With a Note by FREDERICK W. PRICE, M.D., F.R.S. Edin.

THAT auricular fibrillation may coexist with angina pectoris is demonstrated in the case of M., a woman aged 72. The value of digitalis when its administration is controlled, not by its empirical dose but by its therapeutic effect, was evident in the treatment of the case.

M. has suffered more or less all her life from cardiac affection, but, notwithstanding the advice of her physician, has for the past ten years led a strenuous life. On several occasions in recent years, she has been compelled by a feeling of general and cardiac weakness to rest for two or three weeks in bed, and to take 7 or 10 minims of tincture of digitalis thrice daily. She regained strength during these rests in bed, but the action of the heart remained rapid and irregular.

In July, 1920, she had a more serious breakdown, associated with breathlessness on exertion, palpitation, frontal and occipital headaches, and several paroxysmal attacks of pain of varying severity. This pain, undoubtedly that of true angina, was situated in the region of the heart; it was sudden in onset, and associated with a feeling of tightness in the front chest, mental perturbation, intense anxiety, and a sense of numbness in the left arm.

The pulse was completely irregular, with a ventricular rate of 124, many of the ventricular contractions not being registered at the wrist. The systolic blood pressure was undoubtedly raised, most of the beats registering 210 mm.; the wall of the brachial artery was thickened. The left border of the heart was one finger breadth outside the nipple line, the right border two finger breadths to the right of the sternum, and the note in the neighbourhood of the junction of the manubrium sterni and right intercostal cartilages and spaces was impaired. There was an apical systolic murmur, propagated to the axilla, and the second sound in the aortic area was rather accentuated. There was an absence of albumin in the urine.

Dr. Frederick W. Price, who was called to see the case, confirmed the diagnosis of auricular fibrillation and true angina pectoris. It is accordingly of special interest to find that in the chapter on auricular fibrillation in his valuable work *Diseases of the Heart*, he states: "It would appear, however, that patients suffering from auricular fibrillation are exempt from definite attacks of angina pectoris." Dealing with the etiology of auricular fibrillation, in the chapter referred to, two main groups of cases are described: "(1) Those with a history of rheumatism, and (2) patients suffering from myocardial degeneration. In the case of the former the condition occurs more commonly in early adult life, and the patients frequently have valvular disease—more often mitral than aortic disease, and more especially mitral stenosis. In the second group of cases the condition is more common after middle age. M.'s case probably belongs to the first group,

since there is a definite rheumatic history, and in view of the long duration of the illness and the presence of mitral regurgitation.

The etiology of the angina pectoris is, perhaps, not so certain; but the supranormal blood pressure, the evidence of thickening of the wall of the brachial artery, and the accentuation of the aortic second sound point to arterial degenerative changes, while the impairment of percussion note in the aortic area suggests the possibility of fusiform dilatation of the ascending aorta.

M. was confined to bed for four weeks, and then very gradually allowed to resume a more normal life. Only a very small quantity of fluid was allowed with each meal, and the total intake of fluid did not exceed 1½ pints a day. Tincture of digitalis was administered during the first week in 15 minim doses thrice daily. At the end of the week, as there was no appreciable improvement, the dose was increased to 18 and ultimately 20 minims. During the second week there was obvious improvement, the ventricular rate gradually falling to 84. As there was now some complaint of general depression, headache, and giddiness, the digitalis was stopped for forty-eight hours, and then recommenced in 15 minim doses. It was found possible to continue with this dose, and the ventricular rate ultimately diminished to 74, and the pulse became much less irregular. The systolic blood pressure came down to 180 mm., a drop of some 30 mm. Coincident with the remarkable slowing and steadying of the heart's action there was a most gratifying improvement in M.'s general condition.

Note by Dr. Price.—I desire to express my thanks to Dr. Hamilton Sandison for allowing me the opportunity of reading his notes of this case, which he kindly called me to see in consultation. The case was undoubtedly one of auricular fibrillation and angina pectoris. The first statement quoted by Dr. Sandison from my book was written towards the end of 1917, and represented my experience up to that time. Since then, however, I had observed two cases of auricular fibrillation (proved by electro-cardiographic examination) who also suffered from typical attacks of angina pectoris, before seeing the case of M., which made the third.

ANEURYSM OF EXTERNAL CAROTID ARTERY TREATED BY LIGATURE OF COMMON CAROTID ARTERY AND INTERNAL JUGULAR VEIN.

BY
W. A. PEVERLEY, M.B., B.S. DUBL., AND J. K. HAWORTH, M.S., M.D. DUBL.

THE following case we think may be of interest and importance.

A Zulu woman, aged about 30 years, came with a tumour of the neck which she said came on after having had a tooth out. There were no signs of injury to her jaw, but she had a swelling the size of a Tangerine orange just below the angle of the lower jaw on the left side. The swelling was expansile in every direction and pulsated visibly. There was a loud systolic bruit over it. The impulse and the bruit disappeared on compressing the artery against Chassaignac's tubercle, and the swelling could be emptied on gentle pressure. It filled up from below on releasing the pressure. The pulsation in the left superficial temporal artery was delayed. The case seemed definitely to be one of aneurysm of the external carotid artery, the only other possibility being a pulsating tumour of the carotid body, and the subsequent history disposed of that possibility.

Following the principle of simultaneous ligation of artery and vein, one of us (Peverley) tied the common carotid artery and internal jugular vein at the seat of election. The after-course was uneventful; the pulsation at once disappeared, and now, six weeks after operation, the tumour is only the size of a small nut, and is hard and fibrous. She had no signs of any cerebral disturbance.

The artery seemed healthy, and she had no syphilitic history, though she had had two stillborn children. A Wassermann test was not done.

It does not appear to be the usual practice to tie the vein as well, though Cœli (Paris Surgical Congress, 1904) proposed the theory and Boari (*Policlinico*, 1905) has found it most successful. It is interesting to note in this regard that Lynn and Shipley (Ochsner, *General Surgery*, 1917) carefully avoided tying the internal jugular vein, thinking, presumably, it added to the risk of the operation. The idea of ligaturing the vein as well as the artery in this case was merely an enlargement of Sir George Makins's principle of simultaneous ligation of vein and artery in

war injuries to blood vessels. It is well to remember that the internal jugular vein cannot safely be tied on both sides.

In the cases recorded up to the present there seems to have been marked success and few or no after-effects when the common carotid artery and internal jugular vein have been ligatured simultaneously.

Memoranda: MEDICAL, SURGICAL, OBSTETRICAL.

HERPES AND VARICELLA.

THE interesting paper by Dr. Carver in the JOURNAL of February 12th induces me to send notes of a case which has come under my notice.

A child aged 7 years was brought to me with severe herpes of the great and small sciatic nerves. There were large confluent masses of vesicles on the right buttock and sacrum to the middle line, down the back of the thigh to the ham, and a few vesicles on the foot and between the toes; the leg below the knee was livid and oedematous. On about the third or fourth day isolated vesicles appeared on the face and forehead, one on the mucosa at vestibule of nose, a few on the trunk and arm, and one on the left leg. These vesicles appeared first as inflamed pimples, then became distinct vesicles which dried up, leaving a small scab. In appearance they were exactly like the pocks of chicken-pox, and if taken by themselves would have been enough to diagnose a mild attack of this disease. The pain in the leg affected was very intense.

Enfield.

FRED. TRESILIAN, M.D., F.R.C.P.

THE following note may be of interest in view of Dr. Carver's letter in the JOURNAL of February 12th:

An only child had well marked chicken-pox, the rash appearing on January 16th last. On February 7th the grandfather, who lives in the house, developed a small "herpetic" eruption over the second costal cartilage on the left side and an isolated spot above the left sterno-clavicular joint. None of the spots became very vesicular. This would be a converse instance to that mentioned by Dr. Carver. The interval was twenty-two days from the appearance of the chicken-pox, but being an only child there was no real isolation.

R. L. HEARD, M.B.

Monkstown, co. Dublin.

THE following cases have some bearing on the alleged association of herpes and varicella:

1. An elderly lady had shingles in 1903. Six weeks after her attack commenced her daughter and son-in-law, who lived with her, were taken ill on the same day with an eruption which their doctor diagnosed as small-pox. The diagnosis appears to have been made because there was an epidemic, supposed to be small-pox, at Cambridge, and the man occasionally travelled in a train which came from Cambridge. As the wife was not exposed in the train, and she and her husband developed the rash on the same day, it seems reasonable to suppose they were infected from the same source—that is, by the patient with shingles.

2. A child, aged 6, living in an isolated country house in a park, developed varicella in April, 1919. The only possible source of infection was that he had, two weeks before, visited a house where the farmer's wife was suffering from shingles.

3. A lady developed shingles on December 29th, 1919. On February 8th, 1920, one of her children, aged 5, developed varicella, and a fortnight later her other two children followed. There was no other possible source of infection to be dis-suit. The interval between the incidence of shingles in the mother and chicken-pox in the child was forty-one days, but the child was not necessarily infected at the commencement of the mother's illness.

4. A boy, aged 14, in March, 1920, caught varicella from his brother, and infected his sister. He had a few vesicles scattered over his body, but between the fourth and tenth left ribs posteriorly was a very copious eruption resembling an extensive eruption of herpes. This looks like a connecting link, as there was nothing to explain the localization of the rash in this neighbourhood.

Bedford.

W. GIFFORD NASH, F.R.C.S.

IN view of the interest excited by the paper of my friend Dr. Carver in your issue of February 12th may I record the following facts?

On January 29th I was attacked with herpes of the left musculo-spiral nerve. For two days previous to the onset of the rash I had some considerable smarting and constant pain all along the course of the subsequent site of the rash, especially at night, and during that period I was convalescing from a rather heavy nasal catarrh.

On February 14th my wife developed varicella, at which time she was convalescing from a severe nasal catarrh. The symptoms and course of this ailment were typical, and I think that it is almost the severest attack of varicella I have seen in my thirty-eight years of medical practice. The rash was profuse and covered practically every part of the body, including the soft palate and pharynx. Thus my wife contracted the varicella sixteen days after I developed herpes, which agrees with Dr. Carver's statement.

Years ago Hilton Fagge stated that varicella rarely occurred in children over the age of 10, and that most writers stated that they had never seen it in adults. It seems to me that the chief point of interest in these cases hovers round the question as to whether this disorder really is varicella, or whether it is not some modified form of herpes zoster. Can anyone tell me if any such cases of herpes-varicella infections have been recorded as occurring in children? We know that herpes zoster is not uncommon in children, and although I have seen a good many cases of varicella in my time, I do not recollect having ever seen a herpes-varicella infection in childhood, and but one other case in adults.

It is, I think, agreed that whereas the fluid from even the mildest eruption of variola is capable of conveying the disorder by inoculation, all, or almost all, attempts to inoculate varicella in the same way have failed. Has any attempt in this direction been made with the fluid of herpetic eruption, and if so, what has been the result? Has it produced herpes or varicella, or has the result been nil?

I may say, in conclusion, that I had not attended or been in contact with a case of herpes or varicella for a considerable time, and my wife, so far as she is aware, had not been in contact with any case of varicella, nor had she varicella during childhood.

Torquay.

G. YOUNG EALES, L.R.C.P., M.R.C.S.

THE following cases have just come under my care, and in view of recent memoranda on the subject in the JOURNAL, I send particulars:

On January 8th last Mrs. B., aged 44, consulted me. She complained of pain in the right arm of a sharp, shooting character, which was about the middle of the upper arm, and radiated to the back of the shoulder. On examination I found a well-marked rash and clusters of vesicles on the back of the of herpes zoster with clusters of vesicles on the back of the of shoulder, inner aspect of upper arm, into the axilla, and on to the chest. On January 22nd her son, aged 13 years, developed typical chicken-pox of a somewhat severe character. The following day the other boy, aged 14½ years, also showed marked chicken-pox.

There was no chicken-pox in the district, none reported from the school attended for two years past, and no trace of contact whatever.

This occurrence would appear to strengthen the contention that there is a common infective agency in herpes and varicella. Another observation common to both is that seldom or never is there intercurrent affection or complications in either disease, and any fatality *per se* I should think does not exist. In passing, it is of a little interest to note that both the boys above referred to, now strong sturdy youths, were born in Guy's Hospital by Caesarean section.

J. GORDON McDougall, M.B., Ch.B. Edin.

Chadwell Heath.

From time to time cases have been reported in which an eruption of herpes was followed within a few days by varicella. Such a case occurred here some weeks ago, and in view of the discussion at present proceeding as to whether there is an etiological connexion between these conditions, it may be pertinent to publish it:

On January 24th a little boy, W. J., was brought to the out-patient department of this hospital for circumcision; when his clothes were removed a typical group of herpes zoster vesicles was found on the left side of the thorax about the sixth intercostal space; the rest of his body was carefully examined for spots, but none were found. His temperature was taken and found to be 98.4° F. Two days later a varicella rash appeared on his chest and back, and his temperature was then 100° F. The eruption was moderately abundant, and the case subsequently ran the ordinary course of varicella.

Inquiry from the mother revealed the fact that a younger brother had had chicken pox three weeks before; no person in the household was known to have had herpes.

J. P. MARTIN, M.A., M.B., B.Ch.

Royal Southern Hospital, Liverpool.

Reports of Societies.

"TWILIGHT SLEEP."

At a meeting of the Edinburgh Obstetrical Society, held on February 9th, Dr. WILLIAM FORDYCE, President, in the chair, Dr. F. W. N. HALLTAIN read a paper on the above subject. Some years ago with Dr. Swift he published the highly satisfactory results of the management of labour under "twilight sleep" in the Edinburgh Maternity Hospital. Since that time a considerable diversity of opinion had been expressed both by the medical profession and by the lay public as to its merits. Though as a rule admitting its benefits, the medical profession had found the supposed difficulty of its adoption in private practice a serious drawback. With the lay public it had been a theme of discussion of the bitterest character. Its ardent opponents had decried it as a most dangerous procedure fraught with the most appalling results. Since his previous paper, he had employed it in every case where the consent of the patient, hospital or private, was obtained—about 800 in all. The results had been correspondingly satisfactory in both. On this occasion he would restrict himself to an account of its employment in private practice. In his last 150 cases thus treated 70 were primiparae and 80 multiparae. In the former there was complete amnesia in 80 per cent. and partial in 20 per cent. In multiparae the amnesia was complete in 50 per cent., partial in 30 per cent., and no effect in 20 per cent., due to insufficient time for the action of the drug to take place, the labour having terminated so rapidly. The treatment adopted in every case was the same. Morphine $\frac{1}{2}$ gr. and hyoscine $\frac{1}{100}$ gr. was given by injection in primiparae when labour was fairly established with pains regular and recurring every ten minutes, and in multiparae whenever definite labour pains were first felt. The patient was put to bed in a darkened room and her ears stuffed with cotton-wool, so that her attention might not be attracted by anything. After three-quarters of an hour a further injection of hyoscine gr. $\frac{1}{100}$ was given, and repeated every hour until labour was completed. If she became noisy or restless after the second stage was reached, chloroform was given during the pains, as from the absence of self-control she might be difficult to manage. After the child was born it was immediately removed to another room to prevent its cries from disturbing the mother during the third stage. She was allowed to sleep till the effects of the drug had passed off; this usually took place in about six hours. When she awakened she was usually unaware that she had ever been in labour.

The largest number of doses given was fifty-three to a primipara with a rigid cervix and strong labour pains, whilst the smallest number of doses which induced complete amnesia was four. It was practically impossible to gauge the amount of analgesia, as the feelings of the patient could not be strictly estimated while under the effect of the drug, and the description afterwards was not to be depended on. Dr. Halltain had little doubt that nearly all suffered discomfort during uterine contractions, which often made them noisy and restless, but of which they had no memory afterwards. It was essential to remember the absence of mental control, as much shouting and restlessness, though it conveys the impression of great suffering to attending friends, was out of all proportion to actual sensation. The feeling of well-being shortly after the delivery was over was perhaps one of the most striking beneficial actions, and tended to endorse the absence of conscious suffering. The effect varied in individuals, hence the acute differences of opinion in both medical and lay minds, and the bitter controversy that existed, and the impossibility of giving a definite opinion without practical experience.

Amongst obstetricians this treatment had been decried in private practice on account of the impossibility of giving personal supervision. This, of course, was necessary if the rules of Gauss were closely followed; he regulated the doses by the memory test. For practical purposes such a regulation of doses was unnecessary. The simple rule of giving an injection of $\frac{1}{2}$ gr. every hour, though perhaps not so scientifically perfect, was sufficient to obtain the benefits required without danger. This could be

done by an intelligent nurse in telephonic touch with the doctor.

So far as his experience showed there was no risk either to mother or child. The latter in 3 per cent. was born oligopnoeic—that is, of a blue colour and with very shallow breathing. In each of these cases it recovered spontaneously without treatment of any kind. In four cases the child was born asphyxiated; three of these were after hard forceps traction, and one in a breech presentation with slight delay in birth of the after-coming head. One child was born dead after craniotomy, having had twenty-three doses to favour head moulding. The patient had had two subsequent healthy children under twilight sleep, labour having been induced at the end of the eighth month. No complications were noted that could possibly be attributed to the treatment. In 6 cases labour was induced, and in none of these did the child appear affected by the drug. Forceps were applied thirty-nine times in the 70 primiparae and twice in the 80 multiparae. This he did not consider more frequent since the use of scopolamine, as he had always followed the rule of using forceps if the head was in the pelvis and the second stage had lasted more than three hours in a primipara and two hours in a multipara. In minor degrees of pelvic contraction he preferred to wait much longer, to permit of head moulding, and in these cases scopolamine was of the greatest advantage in diminishing the suffering during the long second stage. He had twice observed patients become so unruly as to be maniacal, trying to bite and refusing to lie in bed. In these cases chloroform was administered deeply and it quickly controlled the symptoms. Occasionally with a long labour he gave a further $\frac{1}{2}$ gr. morphine, where much restlessness was experienced before full dilatation of the cervix. Morphine had been credited with being the cause of the oligopnoea. This he was not prepared to admit, as very much larger doses were given in eclampsia without such evil effects.

Dr. HALLTAIN had not used this method much in private practice because early in his experience with it he had had a stillborn baby, and though he could not say definitely that twilight sleep was the cause of death, he had been very careful about using it since. Careful records had been kept of its use in 320 cases in the hospital, and with the exception of vagaries in some of the patients' behaviour, and some difficulties in resuscitating the babies, it was very successful. He had noticed that where the primary dose of morphine and scopolamine was followed by the birth of the child about $3\frac{1}{2}$ hours afterwards these babies were difficult to resuscitate. Where the labour occurred either under two hours or was considerably later than $3\frac{1}{2}$ hours after the primary injection, there was no difficulty at all. If the infants continued longer in the uterus the effects of the morphine wore off, and if they were born before two hours the morphine had not had time to have a bad effect. He had formed the opinion that the method was a valuable adjunct to chloroform, and it had the advantage, unlike chloroform, of being useful during the first stage of labour.

Dr. HAIG FERGUSON agreed with all that Dr. Halltain had said regarding the use of twilight sleep in private practice. It was not so valuable in hospitals, where the bustle and commotion incidental to hospital work were against its success.

Dr. LAMOND LACKIE gave the statistics of the use of twilight sleep in 91 cases in the Edinburgh Maternity Hospital. The initial dose was morphine $\frac{1}{2}$ grain and hyoscine $\frac{1}{100}$ grain. As regards subsequent doses, $\frac{1}{2}$ grain of hyoscine was repeated every hour till the head was on the perineum; $\frac{1}{2}$ grain of morphine was repeated in only a few cases. No patient had more than twelve injections and the average number of injections was seven. The results in regard to the mother were good. As regards the children, in 77 cases—that is, 84 per cent.—there was no bad effect. In 9 there was slight cyanosis—that is, 10 per cent. Prolonged artificial respiration was required in 3 babies—that is, 3.3 per cent. In 2 cases there was no apparent cause, in the third the child was born within two hours of the last injection of morphine. There had been two deaths, but in one case version was performed and in the other craniotomy.

Dr. RONALDSON had used hyoscine for the last ten years in private practice, and in practically every case, and he would as soon think of going without it as without chloroform.

Dr. FLEET said he had found the method of enormous benefit in general practice, and if one had an efficient nurse it could be given in every case.

Dr. HENDRY (Glasgow) did not agree with Dr. Haultain regarding the definite interval administration of the drug without any reference to the condition of the patient, because he found that patients were susceptible to scopolamine in very different degrees.

Dr. R. W. JOHNSTONE agreed that twilight sleep was a valuable addition to the methods of treating labour. The best results were obtained when the doctor was in fairly constant attendance, and where the dose was regulated by the patient's reaction.

Dr. F. J. BROWNE, during his work upon stillbirths, had found, out of 300 necropsies, four cases in which he considered himself justified in putting down the cause of the death of the child to morphine-scopolamine narcosis.

Dr. KERRIE PATERSON said he had given up twilight sleep in practice because of one unfortunate experience with the child.

EXOPHTHALMIC GOITRE.

THE discussion on exophthalmic goitre in the combined meeting of the Clinical Section of the Royal Society of Medicine with the Sections of Medicine and Surgery, which was adjourned from February 11th, was resumed on February 25th, Sir ANTHONY BOWLBY presiding. A report of the opening of the discussion appeared in the BRITISH MEDICAL JOURNAL of February 19th at p. 268.

Mr. DONALD ARMOUR, who dealt with surgical treatment, objected at the outset to the terms in common use for describing the disease, and urged that a wider use be made of the term "hyperthyroidism." He said that in operating he had always used a general anaesthetic. The anaesthetic bogey was disappearing, but it looked like being replaced by another bogey—namely, the possibility of damage to the recurrent laryngeal nerve. This danger need not arise if care and gentleness were exercised in operation. The ligation of arteries had a definite place among the operative procedures. He had been impressed by the excellent results obtained from ligation alone. The ligation of the vessels and the removal of more or less of the gland substance were the only two operations which should have any place in the surgical treatment of the disease.

Dr. FLORENCE STONEY gave particulars of some 200 cases which she had treated by x rays during the last thirteen years. Of these, 78 were quite cured and strong after a long interval since cessation of treatment, 66 were much better, 28 were no better; many of the others had been lost sight of. X ray treatment should only be entrusted to a first-class radiologist. If time was of vital importance in any case, surgery might offer the greater advantage; in all other cases x rays should be preferred, since they spared the patient the mental upset of operation, sometimes repeated, as well as the pain and risk to life. The disadvantages of x rays were the tediousness of treatment—largely obviated by taking the disease in hand early—and the occurrence of telangiectasis and scars, both of which, however, occurred less and less frequently with improvement in technique.

Dr. J. M. H. CAMPBELL brought further up to date Sir William Hale-White's analysis of the after-history of cases at Guy's Hospital. During the ten years 1908-17 reports were available of 127 cases at Guy's, of which 80 or more had been traced, while 8 had died in hospital either from the exophthalmic goitre itself or from terminal affections while this condition was acute. Of the cases traced after discharge, 7 were found to have been completely cured, 26 almost cured and able to live a normal life, 29 much improved and able to do light work, and 11 improved slightly or not at all. A comparison of the results of surgical and medical treatment—the former only applying to a small number of cases—showed much the same proportions in each of these four groups.

Mr. W. H. C. ROMANUS discussed the selection of cases for operation. If all the signs and symptoms were slight and not progressing, medical treatment was often followed by benefit. In moderately severe cases or cases in which any one sign or symptom was present to a marked degree, medical treatment should not be continued for more than two or three months at most. Operation should not be urged in those cases where the patient was very unwilling to undergo it. The removal of large portions of the thyroid

gland was the procedure which gave the best results. One lobe, the isthmus, and a quarter of the other lobe was the minimum which should be excised. After thyroidectomy it was very common to find a greater improvement in the subjective symptoms than in the physical signs.

Mr. A. J. WALTON spoke of the results in 101 cases in which operation had been done; 52 were completely cured, and 23 relieved, and there were five deaths. These were selected cases in the sense that they had all received medical treatment; they were the failures of medical treatment. It was his custom never to operate on cases during the first six months. His opinion of x ray treatment was unfavourable. He advocated medical treatment (1) if the symptoms had been in evidence for less than six months; (2) as a preliminary to surgical treatment; (3) before a second operation in a case of relapse, where there was an enlargement of the remaining portion of the thyroid after operation. He divided the disease into three groups: the type which was predominantly vascular, the type which was predominantly nervous, and the type in which hyperthyroidism was in association with adenomata. The last ought not to be included with exophthalmic goitres. The vascular type did extremely well after operation, the nervous type not so well, though he thought operation should be done. He always did a partial thyroidectomy; he had never done ligation of the artery, though he did not condemn that operation.

Mr. J. E. ADAMS thought that the unfortunate results obtained by surgery in the past were due to the use of chloroform as the anaesthetic, and to the failure of surgeons to recognize the necessity for gentle handling in thyroid surgery. The great merit of local anaesthesia was that it compelled the surgeon to be gentle. He suggested that radium therapy might be combined with surgery. A hemithyroidectomy might be done under local anaesthesia, followed by the burying of radium in the wound for a number of hours.

Dr. F. HERNIMAN-JOHNSON was doubtful if x-ray treatment, unless used in large doses, had any inhibitory effect on the gland, yet its beneficial influence was very marked in many cases. He believed that the good effects were constitutional rather than local, were general and not specific. Small and frequent doses were necessary, at any rate at the beginning of treatment. In difficult chronic cases it might be well to use galvanism as well as x rays. X rays and electricity were part of the medical treatment of exophthalmic goitre, and the time to call in their aid was when the disease was first noticed.

Professor H. G. EARRLE gave a short description of the basal metabolism test for hyperthyroidism, demonstrated an instrument, and showed a number of graphic tracings of the measurement of oxygen consumption.

The discussion was then further adjourned till Friday, March 11th.

CONGENITAL SYPHILIS.

A discussion on congenital syphilis, its diagnosis and treatment, was opened on February 25th at the Royal Society of Medicine, in the Section for the Study of Disease in Children, with Dr. FREDERICK LANGHARD in the chair.

The Limits of the Wassermann Reaction.

Sir HUMPHRY ROLFSTON restricted his opening remarks chiefly to the suggestion of lines for discussion. He spoke first of the limits of the Wassermann reaction as a means of diagnosis, and then of the influence of congenital syphilis in favouring the onset of other infections, in leading to changes in the endocrine glands, and in bringing about other conditions not generally regarded as being due to syphilis nor obviously connected with endocrine gland lesions. With a certain number of exceptions, most of which hardly came within practical range, a positive Wassermann pointed to the presence of active syphilis and to the need for antisyphilitic treatment, but the converse did not hold good, and the question for consideration was, in what circumstances should they hesitate to accept a negative Wassermann as evidence that syphilis was absent and treatment unnecessary? The syphilitic infection, after severely damaging an organ, might die down or die out, and although its past effects were obvious, it was no longer an active factor. In such cases, if the

Wassermann test was negative, it might logically be argued that antisyphilitic treatment was unnecessary; the conditions which he had in mind were insufficiency of the glands of the internal secretion and of the blood-forming organs. Was a negative Wassermann of the blood to be regarded as final evidence that antisyphilitic treatment need not be undertaken, and that the possibility of further activity of the spirochaete, perhaps on the endocrine glands already affected, could be ignored? He suggested that at present it was impossible to adopt as an absolute proposition that in the presence of syphilitic stigmata a negative Wassermann eliminated the possibility of existing syphilis.

Remote Effects.

In the second part of his remarks Sir Humphry Rolleston pointed out that congenital syphilis was a factor disposing to other infections. A number of acute infections were so well marked as often to mask the underlying syphilis. The influence of syphilis was also very important in the causation of lesions of the endocrine glands, and so indirectly of syndromes which were not necessarily characteristic of syphilis. The pituitary body might be infected, and its infection might perhaps be accompanied by a negative blood Wassermann, although a cerebro-spinal Wassermann might be positive. Among various other conditions, obesity was seldom recognized clinically as a result of congenital syphilis; nevertheless it occurred. Another problem of extreme difficulty was the part which insufficiency of the endocrine glands played in some of the obscure bone diseases. There were at least three ways in which congenital syphilis might be imagined as giving rise to chronic interstitial nephritis: by means of the fibrotic process following on an acute interstitial nephritis, by the production of arterio-sclerotic kidney, and as a result of damage to the endocrine glands, the last having a definite bearing on infantilism. No discussion of the remote effects of congenital syphilis would be complete without a reference to rickets, and he touched in passing on the recent interesting suggestion that syphilis so damaged the endocrine glands that the bones were sensitized to such immediate causes of rickets as diet deficiency.

Surgical Manifestations.

Mr. O. L. ADDISON, who opened the discussion from the surgical side, said that the manifestations of congenital syphilis which came to the surgeon were, on the whole, less puzzling than those which came to the physician. The chief factor in the successful diagnosis of most diseases was to be on the watch for them, and it was a commonplace that syphilis was the best masquerader of them all. At present they seldom saw the severe manifestations of congenital syphilis except in infancy, and with antenatal treatment it might be hoped that even in infancy they would become rare. The most constant feature of infantile syphilis was osteomyelitis of the long bones. He had frequently caused radiographs to be taken in doubtful cases to confirm the syphilis diagnosis. The diagnosis offered little or no difficulty if such radiographs were taken. In the second period, following upon infancy, bone and joint affections were still the most marked manifestations. Periostitis was very common from three years onwards, either diffused or localized, and was frequently found in either form on the tibia, though it might occur on the other long bones as well. Mr. Addison showed a large number of radiographs illustrating the various bone conditions. He added that he had only had one case in which he was able to prove the presence of both syphilis and tubercle. He believed in a course of novarsenobillon plus mercury, and of the two drugs he did not doubt that mercury was the more valuable.

Juvenile General Paralysis.

Sir FREDERICK MOTT exhibited some photographs and photomicrographs relating to juvenile general paralysis and tabo-paralysis as a result of congenital syphilis. These included cases of general paralytics as old as 15 years in whom the sexual organs were quite undeveloped. Long ago he was convinced that syphilis was the cause of general paralysis, and not alcohol or sexual excess, or any of the other causes which had been sometimes cited, and he felt that the only way to demonstrate this was to collect cases of juvenile general paralysis and prove their syphilitic origin. About half the cases collected showed definite

signs of congenital syphilis on the body, but the remainder had no signs on the body exteriorly, and he had to get the family history, which he was able to do in the majority of cases. The family history seemed frequently to show a record of three or four miscarriages followed by the birth of a juvenile paralytic. The juvenile paralytic seemed to be the last development of the familial disease. With regard to the infection of the pituitary body, there was no doubt that spirochaetes were in the brain in every case in which there was a positive reaction of the cerebro-spinal fluid, but he had examined some pituitaries and had never seen the spirochaetes in the pituitary body.

The Wassermann Reaction from the Clinician's Standpoint.

Dr. LEONARD FINLAY (Glasgow) said that, although most of the enigmas regarding the Wassermann reaction had emanated from the laboratory, he as a clinician had the greatest faith in the reaction, which for all practical purposes he regarded as specific. He took a number of cases of what might be supposed to be the early manifestation of syphilis—cases of different skin manifestations sent up by his colleagues to the hospital—and divided them into four classes: (1) those which, clinically, were definite syphilis; (2) those with regard to which he was doubtful but was inclined to think syphilitic; (3) those which he was inclined to regard, though still doubtful, as not syphilitic; (4) those which, in his opinion, were definitely not syphilitic. The results of the subsequent Wassermann test were as follows:

		Positive Wassermann.	Negative Wassermann.
Class 1	...	181	2
Class 2	...	31	10
Class 3	...	11	40
Class 4	...	0	58

The mothers of syphilitic infants showed a positive Wassermann reaction in 76 cases; a negative in 10. He had also analysed the Wassermann reaction obtained in a considerable number of different conditions, and in presenting a list of these he pointed out that of the 13 cases of congenital heart disease included not one showed a positive reaction, and of the 14 cases of marasmus one was positive and the others negative. His general impression from working on Wassermann reactions in a children's clinic was that congenital syphilis was nothing like so frequent as was commonly stated. The only way to arrive at a conclusion on the subject would be to obtain the Wassermann reaction in a large number of cases admitted both to the indoor and outdoor departments of the hospital, and, so far as he knew, this had only been done in America, where the proportion of congenital syphilis was stated to be 2 per cent.—meaning 2 per cent. of the ailing child population only. If a positive Wassermann spelled syphilis, a negative Wassermann spelled no syphilis—at least, in the presence of no active manifestations. He condemned treatment by mercury alone; 70 per cent. of the children he had treated in the old days by mercury alone had died, but with the introduction of salvarsan and its administration along with mercury (he never used salvarsan alone) the mortality fell at first to 36 per cent. and later to 26 per cent. He had had a good many accidents when attempting to give salvarsan intramuscularly, and preferred the intravenous method of injection. With regard to ante-natal treatment, not only was the child who was born immediately after a course of treatment healthy, but children born subsequently of the same mother appeared to be healthy too. He advocated the encouragement of ante-natal treatment by, among other means, the compulsory notification of miscarriages and stillbirths.

Ante-natal Treatment.

Dr. AMAND ROUTH said that about 16 per cent. of infantile deaths were due to congenital syphilis, and he pointed out that the reduced infant mortality for the years 1917-19 did not hold good so far as the early weeks of the infantile year were concerned. He doubted whether early syphilitic abortions could be prevented by ante-natal treatment with salvarsan, partly because the diagnosis of pregnancy could not be obtained early enough, and partly because, if the infection was sufficiently active, the delicate embryo would be destroyed. With our present knowledge, congenital syphilis could be prevented or cured if every syphilitic mother were treated, not only during pregnancy,

but in anticipation of her next pregnancy, especially if the treatment of the child were continued after birth; for it was clear that the most serious cases of embryonic infection would terminate in abortions or still-births, and that almost all other cases, owing to the infection being latent, were amenable to treatment during pregnancy. To begin the treatment of a congenital syphilitic child only after its birth, when it had probably a positive Wassermann reaction, was very rarely effectual.

Results of Treatment of Children.

Dr. D. N. NABARRO related some of his experiences at the venereal diseases clinic at the Children's Hospital in Great Ormond Street. He said he was in the fortunate position of himself doing the Wassermann tests as well as treating and watching the cases. He was convinced that the Wassermann was an extremely valuable test when reliably done, but it was often not done reliably. During last year he had treated 77 patients with 530 injections. The injections (of, until this year, novarsenobillon) were always made, if possible, into the veins. Several children had had from 18 to 24 injections. He had no doubt that many children had benefited considerably from the treatment. In three interesting cases ulceration of the palate had healed up. He was not sure that, in eye treatment, the condition of keratitis had been shortened. Periostitis had cleared up in a remarkable manner. A certain number of mentally defective children became definitely brighter. But, in his experience, the immediate results in the treatment of congenital syphilis were not so dramatically obvious as in the primary and secondary stages of the acquired condition; and many of the cases died. Of a group of 62 children treated last year, 14 became negative; but of these 14, 5 had again become positive.

Statistics of Blind Children.

Mr. BISHOP HARMAN described the associated symptoms found in 600 cases of children blinded from the effects of congenital syphilis. He stated that the cases were the collection of seventeen years, that they had been under his care for an average time of six years, so that there was ample opportunity for observation. Dividing the cases in two groups as the front or back parts of the eyes showed the most manifest inflammatory effects, he found 398 cases of interstitial keratitis and 229 cases of disseminated choroiditis. Amongst the group of interstitial keratitis the main associated symptoms were: Hutchinson's teeth 265, characteristic physiognomy 115, iritis 128, bad family history 170, scarred mouth 61, bone or joint disease 26, ulceration of nose or palate 15, deafness 63. Among the group of disseminated choroiditis, numbering 229, there was optic atrophy in 117, Hutchinson's teeth 97, physiognomy 53, bad family history 115, bone or joint disease 19, deafness 51. Comparing the frequency of the chief associated symptoms of the two groups it was found that of the characteristic teeth were present in 73 per cent. of keratitis and in 46 per cent. of choroiditis, bad family history in 47 per cent. of keratitis and 55 per cent. of choroiditis, gross mental disorder in none of the keratitis cases but in 41 per cent. of choroiditis. Bad family history was shown by the high rate of miscarriage, still-birth, infant death, and diseased children. Among 150 syphilitic mothers there were 1,001 pregnancies with only 390 presumed healthy children. Amongst 150 average hospital patients who were mothers there were 826 pregnancies with 654 healthy children, or 792 per 1,000, so that the average mothers produced twice as many presumed healthy children as the syphilitics. Mr. Harman advocated the value of ante-natal treatment.

The discussion was adjourned until March 16th.

ANAESTHETICS IN PLASTIC SURGERY.

A MEETING of the Section of Anaesthetics of the Royal Society of Medicine was held on February 4th, with Dr. SHIRLEY, President, in the chair, and a paper by Messrs. ROWBOTHAM and MAGILL on "Anaesthetics in the plastic surgery of the face and jaws" was read, based on 3,000 cases at Queen's Hospital, Sidcup. After alluding to the physical and mental peculiarities of the type of patient and to the number of times each of them generally required an anaesthetic, the authors divided the cases into those in which the anaesthetist has control of the mouth

and those in which he has only the nose at his disposal. In all cases the main difficulty is that of maintaining a proper airway. When the mandible is altogether or largely missing a long blunt instrument is employed through the mouth to hold up the base of the tongue during induction. Technique was described rendering possible the use of nitrous oxide for induction in patients with broken or abnormal jaws. Intratracheal insufflation proved to be the most generally applicable method. The authors had devised means for employing gas and oxygen with this method, generally combining the gases with small amounts of ether. The methods of passing the catheter through the nose and guiding it into the larynx by specially devised instruments were described. Frequently dilatation of the nares by a series of tubes was required, and often a tube was used through each nostril. The use of nitrous oxide, with or without the aid of local infiltration, was described in connexion with superficial flap operations. The necessary steps were described for avoiding chest complications, which are to be feared owing to the length of time required by most of the operations dealt with. These averaged one and three-quarter hours and were often over three hours. In 1,700 cases there had been only four instances of bronchitis and two of pneumonia.

In the discussion which followed, Mr. H. E. G. BOIRE feared that the dilatation of the nose as described was very likely to cause bleeding. His own experience of passing nasal tubes was that although one side of the nose was usually free it frequently happened that it was almost impossible to pass a second tube through the other nostril. He believed that colonic oil ether anaesthesia was too uncertain for the class of case discussed, and also that the long unconsciousness afterwards was a drawback. His present preference for these operations was a combination of gas and oxygen and CE mixture. Mr. RAMSEY PHILIPS pointed out that a catheter passed through the nose could usually be guided into the larynx by altering the position of the patient's head without using an instrument through the mouth. Dr. W. J. McCARDIE said that in a large experience of the kind of case dealt with by the authors he had used very simple methods. Nasal or oral intubation with "draw-over" inhalation from a mask or plain gauze had generally given good results. Nasal tubes should have large lumen and be comparatively stiff. There were certain advantages in the use of chloroform for these cases, such as little oozing and quiet respiration and circulation. Mr. KIRKBY THOMAS said that he induced with CE mixture from an open mask, passed a wide rubber tube down into the pharynx and packed this round with gauze, and then passed the delivery catheter of a Junker's inhaler into the tube. The catheter was kept in position by pressure against a safety pin transfixing the pharyngeal tube. Dr. F. E. SHIRWAY considered intratracheal ether far superior to the older methods for these free operations. Nasal tubes frequently caused damage with considerable bleeding, and he believed that there was a risk of conveying septic infection if a catheter were passed through the nose into the trachea. Mr. C. W. T. HINSEN described a tap for allowing small portions of ether to be taken up when it is required to supplement gas and oxygen with this anaesthetic.

MEDICAL REFORM IN IRELAND.

At a meeting of the Section of State Medicine of the Royal Academy of Medicine in Ireland on January 14th, the President, Dr. R. J. ROWLETT, opened a discussion on "Medical reform in Ireland." He gave an abstract of the recent report of the Irish Public Health Council, and expressed the opinion that it gave the foundation for a thorough and statesmanlike scheme of reform. Unfortunately the Government had declined to legislate on it, and the Chief Secretary had given contradicting reasons for this refusal. The scheme might, however, form the basis of legislative action when a normal system of Government again existed in Ireland. It was a hopeful sign that those who represented the political opinions of the majority of the Irish people had serious and sound views on health matters. Sir JOHN MOORE, President of the Academy, read a paper on "Existing hindrances to public health work in Ireland," in which he drew attention to the fact that the Infectious Disease

(Notification) Act of 1889 provided that the local authority should pay to the medical practitioner a fee of half a crown for each certificate sent by him in accordance with the Act if the case occurred in his private practice. This provision was endorsed and extended by the Infectious Diseases (Prevention) Act of 1890. The Tuberculosis Prevention (Ireland) Act of 1903 provided that a fee of one shilling should be paid to the practitioner for certificates in the case of persons treated in public institutions and half a crown if the case occurred elsewhere. The Local Government Emergency Act of 1916 reduced the fee payable for notification to one shilling in all cases. With regard to the sanatorium treatment of tuberculosis, he referred to the extraordinary fact that an *impasse* between the Local Government Board and the local authorities should be allowed to cause serious risk to public health by interrupting the machinery provided under statute for dealing with tuberculosis. Lastly, he pointed out that the recommendations and proposals of the Irish Public Health Council, a statutory body, had been for the time being stultified by the decision of the Government that schemes involving expenditure and not yet in operation were to remain in abeyance.

Mr. BURKE said it was very hopeful to find medical men of the political views and professional standing of Sir John W. Moore and Dr. Rowlette putting Irish public health before every consideration. It was gratifying that such pioneers of public health in Ireland were so explicit in attaching responsibility to the Government for the threatened, and in some places actual, suspension of the health services in Ireland. The present deplorable condition of public health in Ireland was for the most part due to the Government's withholding grants which heretofore were given towards public health administration, but now were diverted to meet the awards for malicious injuries. Dr. MOORHEAD said he had been lately studying the financial position of the voluntary hospitals, and concluded that the only hope for the future lay in some form of State subsidy or grant. He hoped that the voluntary basis would always be maintained. When the combined sums of voluntary subscriptions, payments from patients who were able to pay, and municipal subscriptions were added together, there would still remain a deficit, and this deficit he felt must be made good by the State. Even if this were done it would not be necessary to have State control, for the municipalities that subscribed to the hospitals sent representatives to the hospital boards, who were welcome and most useful members. Similar representatives of the State would add strength to the hospital boards in the future.

Sir WILLIAM J. THOMPSON, Registrar-General, said he did not think even the profession fully realized the amount of invaluable work done for public health by Sir John W. Moore, Dr. Rowlette, and Dr. Alice Barry, who were selected by the Irish medical profession to represent their interests on the Irish Public Health Council.

At a meeting of the Brighton and Sussex Medico-Chirurgical Society held on February 3rd, Dr. W. LANGDON BROWN, discussing types of glycosuria and their treatment, said that although carbohydrate formed more than 70 per cent. of ordinary diet, it only constituted about 1 per cent. of the body; it was, therefore, the most easily metabolized of the foodstuffs, and disturbed metabolism was apt to show itself particularly in respect of carbohydrate. That true diabetes implied a great deal more than a mere disturbance of carbohydrate metabolism was now recognized; it was a disease characterized by exaggerated katabolism, which shows itself first and most obviously in respect of carbohydrates. He then discussed the various ways in which the body normally dealt with carbohydrates, and pointed out that it attempted to compensate for an impaired power to assimilate them (1) by storing more than usual as fat in the earlier stages, and (2) by raising the "leak point" for sugar, thus diminishing its escape. In some persons the leak point was abnormally low, constituting renal glycosuria, which could usually be recognized by the constant output of sugar, irrespective of diet. Since the sugar in the blood and in the urine did not run parallel, owing to variations in the leak point, it was important to know what was happening in the former. A single observation was not much use; it was far more helpful to give a dose of sugar and watch how the body was able to dispose of it by estimating the blood sugar at regular intervals.

Reviews.

BRAIN INJURIES.

THE book on *Brain Injuries* by Dr. W. SHARPE, of New York, is divided into three parts, of which the first deals with the diagnosis and treatment of brain injuries; the second with what are termed "acute" and "chronic" brain injuries in adults; and the third with brain injuries in children.

The author rightly insists upon the preponderating importance of the cerebral over the cranial injury, but the main theme, developed at great length and with much needless repetition, is concerned with variations of the intracranial pressure. Almost all the symptoms and sequelae of cranial injuries, whether headache, giddiness, mental deterioration, or even traumatic epilepsy, are ascribed to increased intracranial pressure. The author has a great deal to say about cerebral oedema, but, although its pathology is discussed, no new light is thrown upon it.

The main bulk of the book is made up of detailed descriptions of a very large number of individual cases, with comments thereon. Six pages, for example, are devoted to a single case. Such an arrangement makes it difficult to look up any given point, and this difficulty is not lessened by the index, which might be greatly improved.

Two pages are devoted to cerebral concussion, and these are followed by detailed accounts of a number of clinical examples. Little, however, can be learnt as to the author's views with regard to the pathology of this much discussed clinical state. He speaks of a "temporary disturbance of the theoretical molecular relationship of the cerebral tissues" and of a "probable combination of an immediate circulatory upset with a greater or less degree of shock." He would appear not to regard as suffering from "true" concussion any patient in whom signs or symptoms of any other form of cerebral injury can be ascertained; "the diagnosis should be made only after all other possible conditions have been carefully excluded." The common occurrence of concussion antecedent to or in combination with any other cerebral lesion does not appear to be recognized.

We have looked in vain for any attempt to discriminate between the now generally recognized types of post-traumatic headache. The pathology of these headaches is not discussed, and they all appear to be ascribed to a general increase of intracranial pressure. Traumatic epilepsy is stated to be "the result of a condition which could have been relieved at the time of the primary cranial injury, and thus the epileptiform convulsions could have been avoided." This view could scarcely be shared by the majority of those with any large experience of traumatic epilepsy. Nor would the method of selection of cases for operation, according to whether the increased intracranial pressure (assumed to be always present) was antecedent to or consequent upon the fits, find general acceptance.

The sweeping condemnation of the closure of cranial defects, and the failure to recognize the symptoms due to the existence of such defects, does not harmonize with the experience which has been gained from the study of the large number of cases resulting from the injuries of warfare. It is not a little surprising that in a book published in 1920 the subject of gunshot wounds of the head should occupy less than two pages.

Perhaps the part of the book which is most open to criticism is that which deals with the alleged advantages of the operation of "subtemporal decompression," particularly in relation to cerebral tumour. It is almost impossible to resist the conclusion that the operation is regarded as a kind of panacea for intracranial lesions. The 73 small pictures which illustrate the steps of the operation show little beyond large numbers of instruments and gloved hands in varying relation with one another. The illustrations throughout are, indeed, not on a high level. For example, the picture on page 92 shows the vertical incision for a subtemporal decompression equal in length to the whole of a hand from finger-tips to wrist.

Diagnosis and Treatment of Brain Injuries. By William Sharpe, M.D., Professor of Neurologic Surgery, New York Polytechnic Medical School, Philadelphia and London: J. B. Lippincott Company, 1920. (Med. 8vo, pp. 763; 220 figures, 7 plates. 35s. net.)

Increased intracranial pressure being the keynote of the book and the arbiter of operative treatment, we look for information as to how it is to be gauged. Naturally, the state of the "so-called optic disks" is taken as a guide, and the author rightly draws attention to the fact that within a few hours of an injury the discs often present recognizable changes, the veins being engorged and the edges obscured by oedema. It is not so easy, however, to accept the oft-repeated statement that the intracranial pressure can be accurately measured by means of a mercurial manometer attached to a needle inserted into the spinal theca.

Amongst the results of cerebral injury in children considerable attention is devoted to the treatment of spastic paralysis. The author examined 1,922 children with this condition, and found ophthalmoscopically and by means of the spinal manometer that 368 of them showed definite signs of an increased intracranial pressure; 358 of these patients were operated upon (subtemporal decompression), with a mortality of 10 per cent. "The results have been most gratifying in the younger children . . . not only has there been a lessening of the spasticity of the arms and legs . . . but there has been a definite amelioration in the mental condition." "Even in the older extreme cases the improvement has been most striking."

A GENERAL VIEW OF PREVENTIVE MEDICINE.

THE avowed aim of the authors of the *Principles of Preventive Medicine*² is "to give an outline of the principles and practice of preventive medicine so far as it seems to concern the medical student and the general practitioner of medicine"; they have succeeded in producing a volume of considerable merit and attractiveness. It cannot be described in any way as a textbook, and certainly will not displace the standard textbooks on hygiene which are read at the present time by candidates for a diploma in public health. It contains much of value to the general practitioner and also to that increasing number of lay persons who are interesting themselves in public health matters. They will learn not only what preventive medicine in the widest sense means, but they will discover what preventive agencies are already in being, how their activities are being carried on, and how the official workers may profitably be assisted by the unofficial.

The general arrangement of the book is excellent. Beginning with a chapter upon the English system of local government, there follow in appropriate chronological succession chapters dealing with eugenics and maternity, infant mortality, the welfare of the child from one to five years—the toddler, the health of the school child, and the health of the adolescent and adult. Later chapters deal with housing, food supplies, water supplies, infectious diseases, preventive inoculation and industrial hygiene. More than forty pages are given to a chapter upon vital statistics in which the elementary principles are very clearly put, and the reader is gradually introduced to more complex phases of the science. In the preparation of this chapter the authors acknowledge the assistance rendered them by Dr. Major Greenwood. The chapter upon preventive inoculation describes with great clearness and simplicity the theory of immunity, and deals with the various methods for the production of artificial immunity. When discussing the subject of alcoholism, the authors express temperate opinions. The solution of the alcohol question, they consider, lies partly in the control of the liquor traffic, partly in the provision of counter-attractions to the public-house, and partly in the education of the people. They add, however, that the question will never be completely solved until overcrowding and slum areas are abolished.

The views of the authors on certain questions are expressed dogmatically and will not find universal acceptance. We need quote two instances only. An ideal system, they say, by which a vast number of unhappy marriages and diseased children might be prevented would be to require the contracting parties to obtain a certificate of health before matrimony. In the opinion of many of those who have given this question serious attention such a course would merely have the effect of increasing the

number of irregular unions. The second instance is in the chapter upon housing, in which is discussed at some length the present-day problem of providing adequate housing accommodation at a rental which the working man will be able to pay. Except in the case of really bad tenants, the authors consider that the provision of wooden houses will solve to a great extent the present and pressing problems of housing. We should be glad if this optimism could be justified. The greater part of the book shows much care in preparation, but here and there are indications of hurried compilation. This is especially the case in the chapter on local government, in which the county council is spoken of as the local authority which has cast upon it the duty of preventing and abating all sorts of nuisances and insanitary conditions and as being responsible for the prevention of disease. We need hardly say that it is the district council and not the county council upon whom this duty falls. Other instances might be given, but we are sure that the slips will be rectified when a further edition is published, as we feel confident will be the case.

X RAYS IN GENERAL PRACTICE.

General Practice and X Rays, a book written by Dr. ALICE KNOX,³ is intended to be a handbook for the general practitioner and the student. It is divided into two parts: the first, dealing solely with the uses of x rays in diagnosis, will be of use to the busy doctor, since it indicates plainly both by text and illustrations the various conditions in which an x-ray examination is indicated, and in what directions it can be of assistance in any particular case. The author shows very clearly that the radiologist is no mere picture taker, but that in his dealings with another practitioner he is a consultant; as it is important that he should be able correctly to interpret the radiological findings he should be treated by the practitioner in exactly the same manner as other consultants, which essentially means that he should be made acquainted with the history of the case and the existing physical condition of the patient.

The first chapter deals somewhat generally with the sphere of usefulness of x rays in general practice, and discusses amongst other things the preparation of the patient for various examinations, the interpretation of plates, and the dangers attendant on an x-ray examination. The second chapter goes into more detail, and serves to indicate what may be expected in diseases of the chest, alimentary tract, the urinary system, the pelvis, and in injuries and diseases of the joints. The third and fourth chapters, which complete this section, are on the diagnosis and treatment of injuries and diseases in children, and on x-ray treatment generally.

Part II, by Dr. Robert Knox, is a short but clearly written description of the production of x rays and of instrumentation. It is quite elementary, but should give anyone who knows nothing about the subject a very good idea of the instruments used by radiologists, and the manner in which x rays are produced and applied.

This book has a distinct purpose: written in plain and simple language, and well illustrated with numerous diagrams and radiographs, it should appeal to all busy general practitioners to whom the usual scientific textbook and the textbooks for experts are altogether too full of detail. The author can be congratulated on having produced for the profession generally a small, well written, and admirably illustrated book which deals lucidly with all the more important points in radiography and radiotherapy, and which can be easily assimilated by the non-expert. It is a book which every general practitioner who has no special knowledge of x rays will find of the greatest use to him in the practice of his profession.

WOMEN AS ARMY SURGEONS.

UNDER the title *Women as Army Surgeons* Dr. FLORA MURRAY has written the history of one of the organizations established by medical women during the war. She relates the history of the Women's Hospital Corps in

³ *General Practice and X Rays*. A Handbook for the General Practitioner and Student. By Alice Vance Knox, M.B., B.Ch., F.R.C.S. London: A. and C. Black, Ltd. (Crown 8vo, pp. 224; 32 plates, 5 figs. 15s. net.)

⁴ *Women as Army Surgeons*. By Flora Murray, C.B.E., M.D., D.P.H. London: Hodder and Stoughton. 1920. (Pp. 263; 25 illustrations. 12s. 6d.)

² *The Principles of Preventive Medicine*. By R. Tanner Hewlett, M.D., F.R.C.P., D.P.H., and A. T. Nankivell, M.D., D.P.H. London: J. and A. Churchill. 1920. (Demy 8vo, pp. 544; 5 diagrams. 21s. net.)

Paris, Wimereux, and Endell Street, from September, 1914, to October, 1919. The record is divided into two parts, dealing respectively with the work in France from September 14th, 1914, to February 17th, 1915, and the long period of more than four years' activity at Endell Street. Early in August, 1914, Dr. Flora Murray, Dr. Louisa Garrett Anderson, and some of their friends, being determined that medical women anxious to give their services to the nation should not be excluded from military work and from the great attendant professional opportunities, energetically collected funds and organized a hospital unit which was established under the French Red Cross in the Hotel Clauville, Paris, by the middle of September. With Dr. Flora Murray as the Administrator or *medecin en chef* and Dr. L. Garrett Anderson as surgeon-in-chief there was little delay in adapting this recently built hotel into a well organized hospital. The story of their experiences, and incidentally of their convincing all and sundry (including both their French hosts and inspecting officers from the R.A.M.C.) that women surgeons could make good, is told with humour and not entirely without digs at the mere men who were "unconverted to women doctors." The foreign language naturally presented some difficulties; left alone on duty a surgeon directed a nurse with the reputation as a linguist to find out if a French officer, shot through the body, had any abdominal pain, the prompt question, "Avez vous du pain dans l'estomac?" elicited an indignant reply that he had taken nothing but the fluid diet prescribed.

In November an additional hospital at Wimereux was organized with the same high courage and spirit, but early in 1915 Sir Alfred Keogh complimented the Women's Hospital Corps on their work and transferred their activities to London and to the charge of a hospital of over 500 beds. The old workhouse of St Giles, Bloomsbury, at the upper end of Endell Street, was renovated and transformed into a hospital and the staff got together. Miss Elizabeth Robins and Miss Beatrice Harraden joined as librarians, and the latter contributes the preface to the volume, in which there is a sincere appreciation of Dr. Flora Murray, followed by the comment:

"It is not to be wondered at that the success of this military hospital, officered, staffed and run entirely by women, became a source of immense satisfaction and pride to all women, but more especially to those who had taken an active part in the struggle for the Suffrage, and had shared with Dr. Flora Murray and Dr. Garrett Anderson the ups and downs, the hopes and fears, the disappointments, disillusionments, and encouragements, and all the stress and strain of a long drawn out political campaign."

The chapter entitled "The position of women under the War Office," contains the story of the unsuccessful struggle to obtain for women doctors serving with H.M. Forces the same rank as men in a similar position.

NOTES ON BOOKS.

The *Minutes of the General Medical Council*,⁵ and of its Committees and Branch Councils for 1920, have been issued. The proceedings of the Council have been reported from time to time in our columns. The bulk of the volume is occupied by the Minutes of the Executive Committee, which fill 121 pages, and by appendices filling 173 pages, the latter being chiefly reports presented by the various committees; the minutes of the Branch Councils occupy 17 pages. The *General Index to the Minutes*⁶ has been brought up to date, and includes Vols. XI to LXI inclusive 1903-1920.

The Early Embryology of the Chick, by B. M. PATTEN,⁷ is designed to assist those who are beginning the study of vertebrate embryology. The author's aim is to describe in a clear and simple form the course of development from fertilization until the end of the fourth day of incubation, so that the student may master the facts easily for himself and so "conserve the time of the instructor for interpretation of the broader principles of embryology." In his account of the early development from fertilization until the time of laying, the author has deliberately avoided controversy, and has given a straightforward, but necessarily somewhat artificial, account of the processes as they

are at present known to occur. The comparison of the gastrulation of the bird with that of the Anamnia will carry conviction only to those who do not realize that the diagrams are the only evidence that is put forward. The author has sacrificed too much for the sake of a clear account. He is asking the student to found his beliefs on something other than actual observation. To the rest of the work great praise is due. The accounts of the various processes of development are clearly explained. The figures are good (there are 182 of them) and the method of direct labelling undoubtedly makes them easy for the student to follow in reading the book. It is like having Dural's Atlas with a clear account of the various stages written alongside. No directions for practical work are given, a wise omission, as they would have increased the size of the work without increasing its value. There is an excellent select bibliography at the end of the book.

BRITISH CHEMICAL INDUSTRIES.

ON February 19th a number of British firms engaged in the production of fine chemicals issued a circular letter pointing out the national importance of the industry, and stating that in the years following 1914 they had, at the urgent appeal of the State, extended their research and manufacturing plant in order to secure those essential products of science without which victory could not be attained. The letter went on to state that this key industry is now in danger, owing to the flood of imports from abroad, which the present condition of the exchanges, among other circumstances, makes possible.

We have since received from a number of old established British firms more particularly concerned with the production of drugs an appeal to medical men of the British Empire to support British industry. The signatories disclaim any political object, desiring merely to lay the following facts before the profession:

"(1) In all fairness, it should be realized that international trading is not on a reciprocal basis, that is to say, foreign chemicals and pharmaceutical preparations are admitted into this country, practically speaking, duty free, whilst goods exported from this country to countries abroad are subject to a heavy duty. One vast country we the import of pharmaceutical while other immense states do not duty already referred to.

"(2) It should be remembered that although much has been done during the war and since in the direction of promulgating British chemical industry, a great amount of work has yet to be done to consolidate the fine chemical and allied industries at home, and an obvious point is that the factories in Germany are for the most part absolutely intact, and she retains secrets which are the outcome of laborious, painstaking investigation.

"(3) We desire respectfully to impress on your readers that we do not advertise to the public, nor 'prescribe,' nor in any way trespass on the rightful province of the medical practitioner; on the contrary, we rely on the position that the chemist, so far as the medical use of chemicals is concerned, is the handmaid of the medical man, and we might add, rather bluntly, we do not recommend foreign medical men and health resorts. Why should the medical man recommend foreign pharmaceutical preparations?"

"(4) The scientific staffs in our laboratories welcome suggestions from medical men, and will carry out investigations to elucidate problems connected with chemistry, materia medica and the like, which may prove of assistance in the art of healing.

"(5) We have in our employment men who have been through the hell of the recent war. We have also with us young pupils and apprentices who have never even heard the name of Lister, and who know nothing of his teaching until we have taught them what he did for suffering humanity. These two types of men, in our opinion, need every support, encouragement and protection which the medical man can give."

The appeal ends as follows:

"We ask the doctor to demand British produce, and furthermore convince himself that what is stated to be British is British, and by so doing enable us to give employment to more and yet more British workmen, and to compete with foreign enterprise on the unequal footing above mentioned."

THE title of the Spanish periodical *Revista de Medicina y Cirugia Practicas* has been changed to *Archivos de Medicina Cirugia y Especialidades*.

DR. ALEXANDER FRAENKEL has resigned the editorship of the *Wiener klinische Wochenschrift*, which he has held for twenty five years.

AN institute of medical bibliography has been established at Naples. Its organ is to be a monthly journal entitled *Rivista della stampa medica*.

THE EPIDEMIOLOGY OF INFLUENZA.

With the exception of a chapter on the clinical aspects, to which reference is made elsewhere, the first part of the Ministry of Health's Report on the Pandemic of Influenza¹ is devoted to the epidemiological study of influenza. The modern history of the disease is first recounted, then the statistics of 1918-19 are examined, next the clinical and the bacteriological features are described. In the four following chapters particular problems—namely, the extent of protection conferred by previous attack, the relation between meteorological variations and epidemic influenza, the epidemiological significance of domestic overcrowding, and the special prophylaxis of the disease—are considered. In the last chapter an attempt is made to summarize the lessons to be learned.

HISTORY.

The historical chapter does not profess to be exhaustive, but examines in some detail the sequence of events from the time of Sydenham. The writers point out the difficulty, amounting to impossibility, of providing a logically complete definition of "influenza," but remark that "if into the definition of influenza, while maintaining the characteristics of *apparent* suddenness, undoubted rapidity of evolution, and usually low fatality, we import the conception of peculiar attendant circumstances, such, for instance, as a break in the uniformity of epidemiological history prior to the outburst, and also keep in mind the catarrhal element of the explosive disease as a frequent clinical experience, we shall reach a plan of identification which is not logically assailable." Following this clue, it is shown that both in the experience of Sydenham and in that of his greatest successor as a medical analyst, Huxham, epidemic influenzas were dramatic incidents occurring in series of years characterized by less striking but yet distinct abnormalities of the public health.

"We think," say the compilers, "Huxham's narrative establishes the proposition that the epidemiological features of the cycle of years within which influenza exploded once or more were, *apart from such explosion*, different from the characteristics of the influenza-free epochs. Huxham's crowded references to intermittents around the explosive manifestation of influenza in 1743, his silence between 1745 and 1752, the paucity of his remarks on the subject during the quiet years 1739-42, are paralleled in the story told by Sydenham. We are also justified in making a comparison between the strange nervous fevers incidental to Huxham's narrative and Sydenham's new fever of 1685. With these long-sustained chronologies by skilful observers to guide us, it is not fantastic to suppose that the inter-relation of 'agues' and influenzas to which Dr. Creighton called attention in the section of his history dealing with the sixteenth and seventeenth centuries, is more than casual and not a mere reflection of some theoretical pathology."

It is shown that similar but less complete evidence exists respecting the influenzas of 1762 and 1782, but that no adequate chronologies of the pandemics of 1803 and of 1831-37 have survived. Both for 1847 and for 1918, there is evidence of an abnormal condition of the public health apart from influenza, but the same remark hardly applies to the years which ushered in the great epidemics of the last ten years of the nineteenth century. Still, even for this latter period—which, as the authors candidly emphasize, constitutes the most formidable objection to the view that influenza is not an isolated event but an incident in a series of related events—prior to the supposed importation of influenza very remarkable localized outbreaks of disease had occurred, such as that at Northallerton in 1887 and the fatal epidemic of pneumonia in Middlesbrough more than a year before the pandemic. The general conclusions drawn by the compilers are in essential agreement with those reached by Dr. Hamer and by Dr. Crookshank; they doubt whether the ravages of influenza can be stayed by the discovery and destruction of some remote endemic focus of the disease, and hold that

"The problem of epidemic influenza is largely an internal problem of each nation; there is no question of shutting the wolf out of the sheepfold, he has been regularly lying down with the lamb for years; his ravages depend as much upon the disposition of the sheep within the fold as upon his appetite. Thus broadly stated, the hypothesis neglects some portion of the truth; however combustible the material, there can be no fire without a spark, and when the fire has been started it may spread to material not naturally combustible. We must not ignore this consideration, but it has perhaps been over-emphasized in current discussion."

RECENT STATISTICS.

In the following chapter the general statistics of 1918-19 are examined. It is pointed out that: "(1) The mortality in England and Wales, as a whole, attributable directly or indirectly to influenza, is without any precedent in magnitude; (2) that that of the metropolis affords no parallel more recent than 1847; (3) that the toll taken at the young adult ages of life is without any known West European or North American precedent." The relation between the death rates from influenza in the three waves and the normal pre-epidemic standardized rates (all causes) of the county and metropolitan boroughs is studied by the method of correlation. It is shown that the death rates in the first wave were substantially correlated with the normal death rates, a finding comparable with that of Professor Raymond Pearl of Baltimore, who showed that in America "an essential factor in determining the degree of explosiveness of the outbreak of epidemic influenza in a particular city were the normal mortality conditions prevailing in that city"; but, for reasons explained in the report, the compilers do not regard their arithmetical results as deserving of much confidence, and suspect that the heterogeneity of the data has influenced the numerical magnitudes of the correlations. The writers devote attention to the form of the epidemic wave in time. They remark that the data of epidemics on ships, carefully compiled by the health authorities of the Commonwealth of Australia, are particularly instructive, that the forms of these curves are complex, almost suggesting in each a triple wave reproducing in miniature the world evolution of the pandemic.

"On the ship we do really have ordinary social life in isolation from the great world, a real microcosm. The remarkable point is that within this microcosm we have seen in miniature a triple wave, such as the whole world experienced, but running through its phases in weeks instead of months. But this evolution was not parallel with the world evolution, since the voyage started after the first act of the world drama. Whatever organism was 'carried,' it must have belonged to the autumn variety, not to the summer vintage. Hence, if this threefold wave phenomenon is not a mere illusion, it would seem to be a function of the organism as modified by passage, a modification determined by the environmental conditions."

BACTERIOLOGY.

The chapter on bacteriology, by Sir Frederick Androwes, is worthy of its author's reputation. At the outset Sir Frederick warns the reader that "the germ theory of disease is now so firmly established that we are in danger of too readily accepting a microbe as the causal agent of a disease, and of neglecting the rigid proofs which should be demanded." He points out that from the experience gained between 1890 and 1918, "it cannot be said that the status of Pfeiffer's bacillus as the cause of epidemic influenza had materially altered. No further confirmation had been obtained, nor had the observed facts disproved a possible relationship." The results in 1918 did not suffice to settle the question. The failures to recover Pfeiffer's bacillus in the summer could not, in Sir Frederick's opinion, be referred to a faulty choice of medium or defective technique.

"Amongst those who have recorded their failure to find the organism are bacteriologists of the highest repute: the failures were perhaps more numerous in Germany than elsewhere; such men as Kolle, Gruber, Friedemann, and many others, failed to find it, while Uhlenhuth and Pfeiffer himself were puzzled at their want of regularity in finding it. It is expressly stated by Sobernheim that, using precisely the same technique, he uniformly failed to find it in the summer epidemic and almost uniformly succeeded in October." "The evidence," says Sir Frederick, "does not carry conviction as to the primary causal relationship of Pfeiffer's bacillus to epidemic influenza. The varying results cannot be correlated with the competence of the observers. The observed facts, notably the earlier negative findings in certain localities, and the more general positive results in the autumn outbreak, would be better explained on the assumption that the bacillus played a very important secondary rôle in the disease, and was not the primary infecting agent." Decisive significance cannot be assigned to the results of agglutination or complement fixation tests because Pfeiffer's organism is at least so commonly present as a definitely pathogenic invader "that it would be strange indeed if antibodies were not formed against it."

Important evidence might be furnished by unequivocally successful results of prophylactic immunization by vaccines containing Pfeiffer's bacillus. Sir Frederick Androwes calls attention to the apparently striking results of large scale inoculations, but notes the desirability of

statistical criticism. This point is in fact taken up elsewhere in the report, where it is remarked that "no inferences can be drawn from a lower attack rate upon inoculated than upon uninoculated persons if the inoculations were carried out during the epidemic, without due allowance for variations of length of exposure." This simple consideration rules out most of the published data. For the rest, the compilers say:

"Such evidence as we have in favour of any practical advantage points to the efficacy of vaccines derived from organisms cultivated from cases existing in the neighbourhood of the tested population. This is illustrated by the example quoted in the section on influenza in the annual report of the Chief Medical Officer. A pure Pfeiffer vaccine was used for the inoculation of employees (volunteers) in a London business house, and the inoculated escaped the disease, while their co-workers experienced a normal incidence. It appears doubtful whether any simple stock vaccine derived from a limited number of strains of micro-organisms implicated in the clinical evolution of influenza is likely to be of value."

It cannot be said that the evidence derived from prophylactic inoculation much strengthens the case against Pfeiffer's organism as the primary pathogenic agent.

Sir Frederick Andrewes thinks that the evidence in favour of a filter-passing organism as the essential cause is suggestive but unconvincing.

"The strength of the case argued by Gibson and his colleagues lies in the fact that there was a definite incubation period in their experiments; that they succeeded in carrying on the effects through more than one generation of animals, and that they produced them with cultures. The weakness lies in the fact that the lesions in their animals do not afford convincing proof of influenza. . . . The cultivation of filter-passing organisms is notoriously a difficult thing, and beset with many fallacies, as Arkwright has well pointed out in his recent criticism of the subject. The results so far recorded in influenza must be received with caution."

Whether or not a primary significance can be assigned to Pfeiffer's bacillus, Sir Frederick believes "there can be no doubt that it played a part of vast importance in the recent epidemic of influenza. Though we know it, at normal times, as a mere agent of catarrh, the more virulent types which prevail in epidemic times are more highly toxic, and seem especially to lead to escape of blood from the smaller vessels in the lungs and bronchi. It seems probable that we must regard Pfeiffer's bacillus as the chief cause of the hæmorrhagic oedema and the localized hæmorrhagic areas in the lungs which have been so conspicuous a feature of the late epidemic." Next in importance come certain types of streptococci; *Streptococcus hæmolyticus* has been often found in the pulmonary lesions, and its presence there has "been a distinguishing feature of the epidemic, especially in the autumn, when the disease exhibited its highest fatality, and it was found in the worst cases."

16. IMMUNITY CONFERRED BY A PREVIOUS ATTACK?

In the next chapter the compilers discuss the question whether those who had been attacked by influenza in one phase of the pandemic were, on that account, less liable to attack in a subsequent outbreak. This matter is examined in detail and perhaps constitutes the most original section of the report. Briefly, the method adopted was this. The histories of considerable samples of different populations were followed through all the phases of the epidemic, and it was determined whether the attack rates in, say, the autumn were significantly different (from the statistical point of view) upon those who had and those who had not been attacked in the summer. It was found that the after-histories of the exposed to risk were very different in different places. In some cases—for instance, in Leicester—those attacked in the summer came off far better in the autumn than those who had not been attacked in the summer; in other cases—for instance, in Manchester—the summer victims experienced an identical rate with that suffered by those not attacked in the summer. The possible reasons for these differences are discussed in detail, and the conclusion is reached that the immunizing value of the strains of organisms probably differed in different parts of the country. The method of analysis is subject to a theoretical criticism. Thus it is assumed that if the attack rates in the autumn upon those who were and were not attacked in the summer are the same, then the summer attack conferred no protection. But if those singled out for attack by the disease in the

summer were so singled out because their resisting power was low, then, *ceteris paribus*, they should again have a higher attack rate in the autumn; if they have only an equal attack rate, the summer experience helped them. But it may be urged in reply that there is little or no evidence that the first phase of the pandemic did select those who, judged by any extrinsic criterion, were peculiarly liable to respiratory attacks. In any event, the practical result that whatever protection was conferred was far from being absolute, is plain. Upon the whole, there is a balance of probability that the summer influenza had some immunizing value; less reason can be shown for thinking that autumn attacks shielded their victims in the third phase.

THE WEATHER.

The following chapter deals with the weather and disease. This chapter contains an interesting summary of traditional opinions and brings out the relation between changes of temperature and variations of mortality from respiratory disease. It also shows that before each of the three waves of influenza warmth was deficient, but, as might have been expected, the compilers hold that whatever part was played by meteorological factors in the genesis of the pandemic must have been quite a minor one.

OVERCROWDING.

In the next chapter the relation between domestic overcrowding and the incidence of influenza is studied; no close statistical relation was found and the tentative conclusion is reached

"that the natural infectivity of the germ may be so high that the necessary exposures and contacts of all persons living under urban conditions are sufficiently numerous to provide opportunities of transfer so effective that any increase above the average is relatively a factor of negligible order."

It is, however, specifically stated that these conclusions apply solely to incidence, not to fatality, it being probable that the fatality amongst patients grossly overcrowded (as, for instance, upon war transports) was far above the average.

Chapter IX deals with general prophylaxis. The compilers remark that

"from what has been said in this report it follows that to avoid crowds, to shield the mouth and nose when coughing or sneezing, not wantonly to thrust one's face into the face of one's interlocutor, are essentially rational and appropriate methods of reducing the risk to take influenza. It even appears probable that the one form of overcrowding which in some little measure can be controlled by the individual is the form most potent to nation, to advise lodgings is indeed a request to seek for public conveyances not grossly overcrowded; but it is quite easy not to frequent theatres, music halls, and picture houses; it is even possible to avoid bargain sales, political meetings, and assemblies. These forms of congestion belong to the extra-domestic group which, by a process of exclusion, we have discovered to be more influential than intradomestic conditions admittedly hard to control now."

Much importance is attached to the hygiene of the nasopharynx, and attention is directed to the researches of Dr. Leonard Hill (described in his reports to the Medical Research Council, and also in our columns). Due weight is given to the importance of further research into the immediate etiology of the disease, but "the public should not suppose either that nothing of service can be attempted until the authentic *materies morbi* of influenza has been unequivocally defined or that the recognition and successful isolation of the authentic microbe would necessarily be followed by elimination of the influenza scourge."

SUMMARY AND FINAL HYPOTHESIS.

The last chapter of this part is a general summary of those we have discussed, and a provisional statement of a hypothesis which covers the facts. This hypothesis is that there have been three phases in the development of influenza.

"The first, which lasted for many centuries, was, if we may be permitted to use teleological language, a series of attempts to maintain a high level of infectivity or dispersiveness, which attempts were unsuccessful. The second phase, ushered in by the year 1889, is marked by a partial victory of the germ, a fairly constant infective power has been secured, and much infection is produced throughout the world at frequent intervals, but the toxicity relative to the infectivity is still slight. The final phase is of complete victory; infective power is maintained, even enhanced, and to this is added a toxicity surpassed

by few epidemiological competitors. Viewed as a contest between man and 'germ,' it would seem that in the congestion of public transport and the multiplication of public assemblies and entertainments, features which increasingly characterize the development of the European type of civilization, a strategical advantage was given to the enemy. Finally, in the provision of countless incubators, whether in garrisons, war-time factories, or abnormally overcrowded and ill-ventilated means of transport and places of entertainment, the opportunity was afforded for the development of destructive powers which secured to the enemy a decisive and overwhelming victory."

These reflections suggest that there are dangers ahead.

"The dangers to the world from epidemic sickness in this matter of influenza are enhanced in two ways. The inevitable trend of the movement of population will keep the infectivity of the organism at a high level. This we may face with equanimity. But if anywhere in the world there be large collections of men, whether through war or economic strife, or through that dissolution of society which a certain degree of collective misery and disorganization entails, herded together *en masse*, there will be opportunities for the other modification of the *materies morbi*, which renders it apt to conquer the world. No sanitary cordon, no quarantine, will shield us from this danger. The porters of the infection may not be sick; to exclude even the sick has often been found a task beyond the power of a quarantine authority; and quarantine has, in fact, never yet succeeded. To realize that the material well-being of the inhabitants of a foreign—perhaps even a hostile—country is a pressing concern of ours is very hard. Yet the teaching of this pandemic is that it is a hard truth. Any supra-national organization for the control of epidemics will need to face it. The popular belief that misery breeds disease is strictly true, and the influenza of 1918-19 is no exception to the rule. The history of the world has never yet provided an instance of a mortal and highly dispersive illness among the antecedents of which human misery did not assume a prominent place."

In his introduction to the volume Sir George Newman emphasizes one aspect of this doctrine—namely, that, as he puts it,

"The fundamental requirement to make us masters of our fate is a universal improvement in the standard of health and the conditions of life. No technical device, no narrow or specific remedy for pestilence, can ultimately triumph apart from a sanitary environment for the community and the sound nutrition of the individual. They are the bed-rock. Out of them spring the sources of national vitality. Hardly less certain is it that we require, and must seek till we find, more use the means; and education is perhaps the answer to that. But in the case of influenza and its allies we are not yet in possession of the means, and whilst we press forward with the improvement of sanitation, of nutrition, and of the conditions of life, we must apply ourselves anew to search and research into the causes of primary and secondary infections, into epidemic catarrh, and the common cold, into carriers, and into immunity. That is perhaps the principal lesson which is taught us by our experience of the great pandemic."

With this quotation from the preface by the Chief Medical Officer we shall conclude our notice of the report. The second part, compiled by Dr. Bruce Low, C.B., and Dr. S. P. James, which compresses within less than 200 pages a vast amount of statistical and other information respecting influenza abroad, does not lend itself to summarization, but is not the less worthy of perusal. The same remark applies to the valuable collection of scientific papers by medical officers of health, as well as by officers of the Ministry, which form appendices to the report.

We believe that Sir George Newman was justified in characterizing this report as a "contribution of exceptional interest and suggestiveness," and that its authors, both the medical members of the Ministry's staff and the other medical men, not civil servants, who have collaborated, deserve the thanks of their colleagues. A volume of 577 pages which announces no sensational discovery and promises no conquest of influenza in the near future cannot render its authors popular heroes. They will, however, be sufficiently rewarded if the outcome of their labours is of use to other students of a menacing yet fascinating problem.

THE Hispano-Portuguese Association for the Advancement of Science will meet at Oporto in June.

A SCIENTIFIC expedition to Central Asia, under the direction of Dr. Roy C. Andrews, has been organized in the United States by the American Museum of Natural History to carry out researches in anthropology, archaeology, zoology, and medical geography in the less explored regions of Turkestan, Tibet, and Mongolia.

UNIVERSITY GRANTS.

THE University Grants Committee appointed in July, 1919, to inquire into the financial needs of university education in the United Kingdom, and to advise the Government as to the application of any grants that may be made by Parliament towards meeting them, has made a report,¹ after giving full consideration to all the representations made to it, and after carrying out a series of visitations to all the universities and colleges in England, Scotland and Wales. The parliamentary grant is now £1,000,000 a year; in 1919-20 a special grant of £500,000 in addition was made, and in 1920-21 the unexpended balance of this, amounting to £196,000, was available. During the past year nearly the whole of this unexpended balance has been distributed. The Chancellor of the Exchequer has promised that the annual vote this year shall be increased to £1,500,000.

The medical member of the University Grants Committee is Sir Wilmot Herringham, who succeeded the late Sir William Osler in November, 1919.

The Committee begins by expressing its sense of the efficiency maintained in the universities and colleges generally in face of many and serious difficulties, but is convinced that the present resources of the universities are inadequate, in spite of the facts that since the armistice the Treasury grants have been increased by 83 per cent., that tuition fees have been increased, that a few local education authorities have increased their support, and that many of the universities are endeavouring also to supplement their revenues by public appeals. On the other hand, it is pointed out that all expenditure, in particular unavoidable expenditure on wages and material, has grown enormously, and that even if the pre-war income were doubled, it is doubtful whether the universities would be as well off as they were before the war.

The report goes on to point out that the number of students since the armistice has been unprecedented; the total number of full-time students in attendance at grant-aided institutions and colleges rose from 23,872 in the academic session 1913-14 to 36,423 in 1919-20, and the number was raised to 37,748 by the addition of certain colleges to the list. Of this total 11,682 were ex-service students, but it is pointed out that a permanent increase over 1913-14 is to be expected, owing to the larger number of secondary schools and to the operation of the Education Act, 1918.

An important part of the present financial embarrassments of the universities and colleges arises out of the need for increased salaries and improved superannuation. The Committee agrees that the present salaries of many university teachers are inadequate, and has evidence that many members of the university staffs are living in circumstances incompatible with continued efficiency; many teachers are not in a position to enjoy the advantages essential to the proper discharge of their duties, such as books, travel and membership of learned societies. Further, many are compelled to supplement their income by dissipating their energies in outside work. The Committee does not commend the scheme of salaries and increases proposed by the Association of University Teachers; it agrees that it would be an advantage if all the grant-aided institutions agreed upon minimum salaries, but does not agree to a dead level of uniformity as between institutions. The Committee also agrees that it is important to establish an equitable system of superannuation. The Federated Superannuation System for the Universities in England, established in 1912, provided that 5 per cent. should be paid by the institution and 5 per cent. by the beneficiary. The contribution of the institution has now been increased to 10 per cent. The youth of the scheme renders it desirable to make special provision for many of the senior teachers. The position in Scotland is special, and is, the Committee thinks, unsatisfactory.

An important section of the report deals with equipment and accommodation, and it is declared that the character and efficiency of a university may be gauged by its treatment of its central organ—the library—which is essential to the well-being alike of the arts and science. Ampler funds are needed and the status of the librarian should be improved. For the subjects included in the faculty of pure science additional staff and improved accommodation and equipment are required. In the

majority of the institutions visited extensions of the chemistry or physics laboratories are either contemplated or in progress, and the needs of the departments of geology, botany and zoology are realized to be hardly less acute.

In dealing with the applied subjects it is admitted that it is not possible to draw a hard and fast line between pure theory and practical application, and in vocational training it is essential to maintain that breadth and proportion of view which are implied by a university standpoint. The bases on which applied science is founded are ever broadening, and as an illustration of the doctrine that university courses must tend to become increasingly exacting if they are to be continually informed with fundamental principles, the following remarks are made about the Faculty of Medicine:

Medicine.

"The Faculty of Medicine is, perhaps, the best example of the combination of the theoretical and practical, the liberal and the vocational, to which we have just referred, and the thorough grounding which it requires in the basic sciences, physics, chemistry and biology, and in the intermediate, anatomy and physiology, illustrates what we believe to be an essential condition of a university education in any applied science.

"It is held by some that the basic sciences should be studied at school before registration, and we are so far in accord with this view that we think that no education can be called liberal which leaves a student at eighteen ignorant of the fundamental laws of Nature upon which rest also the processes of the arts. But there are at present too few secondary schools in which these subjects are properly taught to allow the universities to dispense with suitable courses for medical students, and also there are special parts of them which are necessary for their application in anatomy and physiology, but are not included in the usual school courses anywhere. The universities, therefore, have not only been compelled to continue to teach these sciences to students of medicine, but have in the last twenty-five years greatly extended and improved the teaching that they provide. Almost within the same time pathology, which in former years was largely confined to morbid anatomy, has expanded so far as to include the vast fields of bacteriology with immunity, and of morbid metabolism, or chemical pathology. It even seems probable that pathology will soon require a physical department, for certain pathological conditions are connected with changes in the blood and other tissues which are essentially physical in character and need physical methods for their evaluation. The whole group of these sciences has passed or is passing into the hands of teachers who devote themselves entirely to the work, and each subject is taught in laboratories which occupy a large amount of space, and are extremely expensive to equip and to maintain.

"The Royal Commission on University Education in London reported in 1913 that the teaching of the final medical subjects in England, though in its practical training of students probably the best in the world, was in some ways deficient in the scientific aspects of the subject. They remarked, and it is generally allowed, that to obtain the best teaching it is essential that the clinical teacher should be himself engaged in the discovery of fresh truths, and should be at the growing point of knowledge. So far as clinical methods can reach, English teachers have no cause to reproach themselves on this score. Accurate observation, which is the foundation of all discovery, has been practised and taught by clinicians in England as thoroughly as anywhere in the world, and up to the present day England has in this field been fully abreast of other nations. But since the middle of the last century, experiment, on the necessity of which Harvey himself insisted, has been applied to medical problems with such increasing vigour and success that the laboratories have become almost as important as the wards. On this side England has been wanting. There has been much brilliant experiment, and much discovery, for instance in diseases of the nervous system, and in metabolism, and in the application of bacteriology; but it has been the work of private individuals who for lack of means have not been sufficiently helped, and often have not even been encouraged, by the schools. It has not been considered a necessary qualification for teaching medicine that a man should have practised this method of advancing it.

"The Royal Commission recommended that to remedy this defect a professorial system should be set up which would provide teachers and an assistant staff willing and

able to devote themselves to scientific investigation. At the instigation, and with the assistance of the Board of Education, whom we have succeeded in the task, this system has been put into operation in certain medical schools in London under the name of "Clinical Units." At such schools directors have been appointed who, entirely or almost entirely resigning private practice, give themselves up to hospital work, treatment of patients, the teaching of students, and the clinical and experimental study of disease. An adequate staff and laboratories have been or are in process of being supplied. Medical and surgical units have now been established, with the assistance of grant-aid from the Treasury, at the medical schools attached to St. Bartholomew's Hospital, the London Hospital, University College Hospital, and St. Thomas's Hospital. At Edinburgh and Sheffield new professorships have been created on a similar basis, and our tour of inspection has shown us that everywhere throughout England and Scotland the principle has been seized, the need realized, and, where circumstances did not admit of such new appointments, great efforts were being made by the present staff to render the teaching more ample and more vivid. The Committee have issued a statement for the guidance of the university bodies contemplating the establishment of new arrangements to this end."

The report contains many references to the importance of evening powers of the universities. The relation of this principle to finance is brought out. The official grant-in-aid provided since the armistice and the further increase promised or contemplated by the Chancellor of the Exchequer prove that the Government and Parliament are not unmindful of their responsibilities, and the expectation is expressed that the claim of higher education upon private generosity will be similarly appreciated. The Committee goes on to emphasize Mr. Chamberlain's reference to local support as a principal factor in future grant allocations, and urges university authorities to regard their endowment funds as the central source of their revenue, "for it is in our view indisputable that only by the consolidation of a stable and substantial income from independent sources can the autonomy and progressive development of a university be assured."

DISEASES OF ANIMALS COMMUNICABLE TO MAN.

PROFESSOR HOBDAY, C.M.G., who holds the chair of therapeutics and hygiene in the Royal Veterinary College, London, gave an address on "Some of the diseases of animals communicable to man" at a combined meeting of the Royal Society of Medicine and the Central Branch of the National Veterinary Association on February 3rd. Professor Hobday began by observing that the study of comparative medicine would throw much light on the symptomatology of disease and on immunity and susceptibility, certain species of animals being refractory or even completely immune to certain diseases. He then went on to point out that the list of diseases communicable from animals to man which exist at the present time in Great Britain comprises at least the following: Glanders, anthrax, tuberculosis, rabies, foot-and-mouth disease, mange of all animals (the horse, ox, camel, dog, cat), ringworm (especially of the horse, calf, cat, and mouse), and certain forms of seborrhoea (such as farriers contract from handling horses with greasy legs). The great prevalence of pyorrhoea in pet dogs, which are so kissed by their fair owners and allowed to lick their lips and hands, should be regarded as a possible factor in the spread of that disease in human beings. Certain parasites require an animal host in order to make their life-cycle complete before they can become pathogenic to man, such as the *echinococcus*, the *Cysticercus bovis* (the larval stage of the *Taenia saginata* of man), and *Cysticercus cellulosae* (the larval stage of *Taenia solium*), the parasites of mealy beef and mealy pork respectively; and the *Trichina spiralis* of the muscles of the pig, which give rise to trichinosis in man in countries where ham is largely eaten smoked, and not necessarily cooked.

Glanders.

Were glanders eliminated from the veterinary schedule, said Professor Hobday, it would disappear as a disease of mankind. In this matter the veterinary profession has to lead the way; that it is doing so is shown by the fact that in 1901 some 2,370 horses (1,823 from London) were destroyed for glanders in Great Britain, whereas during

1920 only fifteen outbreaks occurred in the whole of the British Isles, and only 22 animals were destroyed, and this after the sale of some 150,000 army horses and mules which had been collected from various countries and employed in the work of the great war.

Mallein is a powerful and an important agent in the disease. By its aid glanders was completely kept under control among the thousands of British horses and mules during the late war in Europe, and I believe that no case of glanders in man was reported; during the South African campaign glanders was terribly rife amongst animals and caused endless anxiety both to veterinary and medical officers.

Some fifteen or twenty years ago, in the districts of London which contained large cab and omnibus stables, it was rare for a County Council veterinary inspector to pass a day without being called in to see a suspected case of glanders, and I recollect one stud of about 2,000 horses from which we got some 90 glandered horses within twelve months. Mallein was then on its trial, and the law did not enforce its compulsory use in in-contact cases, the consequence being that when the owner of the stable had an outbreak of glanders he promptly sent the in-contact animals to a repository, and thus disseminated the disease broadcast. Twice I have officially been present at the *post-mortem* examination of men who had died of the disease, and in neither case was the disease suspected until just before death; one patient was treated for pleurisy and the other for rheumatism.

At the present time mallein is compulsorily applied by law to all ponies before they are sent underground for colliery work, and when an outbreak takes place in any stud or stable in any part of the British Isles the whole of the in-contact animals are immediately quarantined and tested. All animals that react are destroyed, and all suspects are set aside and re-tested, until the veterinary inspector is satisfied that a clean certificate can be given to the stud. During the late war special precautions were taken by the officers of the Royal Army Veterinary Corps to isolate and apply mallein to all animals on purchase, and again on admission to, and evacuation from, veterinary hospitals. Mallein was administered to all units at regular intervals and when finally sold either for work or for human food all were submitted to this test. In this way millions of doses were used, but the result justified the trouble taken, and no army of the whole allied force was so free from glanders as ours.

The infection is usually transmitted to man from a glandered horse, ass, or mule, by the discharge from the nose or a farcy bud, or by contact of an abraded surface with a sponge or brush, or other stable utensil, which has become contaminated with some of the infectious discharge from the animal. The possibility of infection of man by ingestion was emphasized by the late Mr. Hunting, Chief Veterinary Inspector of the London County Council, who observed men handling the nostrils of infected horses, and then eating their bread and meat, or bread and cheese, without washing their hands. The men most commonly affected are those whose life brings them into contact with horses. I believe I am correct in stating that there is only one instance on record in which a human patient has survived and permanently become clear of a glanders infection—the fortunate man being a well known member of my own profession; but it was only after endless operations and several years of painful treatment. One of those who died of this disease last year was a veterinary bacteriologist of the Government of India, a man of great promise, the disease being contracted during his course of duty. Among carnivorous animals glanders has been observed in lions fed in a zoological garden on infected horse-flesh which was given raw.

Anthrax.

Anthrax still takes its toll of both animal and man, being met with in man principally amongst those who have to deal with animal products, such as skin, hair, wool, and hides from abroad; and those who make, or assist, at *post-mortem* examinations on dead animals. The infected Japanese shaving brushes is another source of danger. The veterinary surgeon sees the disease most commonly in cattle, although it is met with in the horse, sheep, pig, and even the dog; in the dog it is rather more refractory than in other animals. The returns of the Chief Veterinary Officer of the Ministry of Agriculture for 1919 show that 180 outbreaks were confirmed in England and 59 in Scotland. In all, 275 cattle, 8 horses, 1 sheep, 38 pigs, 1 dog, and 7 ferrets were affected; 25 per cent. of the outbreaks took place on premises where anthrax had occurred during the previous year.

Owing to the precautions taken by the officials of the Ministry, the number of outbreaks has been reduced from

an average of about 1,000 annually between 1907 and 1910 to 239 in 1919. If only the disinfection of imported hides, wool and hair, etc., can be thoroughly controlled, we shall hear of fewer cases in man, and the same may be said in regard to the supply of cottonseed and other cakes imported into Great Britain as a food for cattle. The surmises made as to the source of the outbreak in 1919 were that it was due (1) to the effluent of tanneries or other similar industries getting into streams, (2) to feeding pigs with infected offal, (3) to the use of imported foodstuffs and artificial manures, (4) to contaminated sewage, and (5) to contact with infected material from other outbreaks. It is by attention to the complete disinfection of animal products and the sources of contamination by animal products that we shall diminish the chances of infection to man. For animals themselves it is a more difficult problem as so much of their food material must of necessity come from abroad, and a good deal of it comes from countries in which anthrax exists to a considerable extent.

Rabies.

For nearly twenty years rabies had until lately no place in this country, and the present inconvenience from which dog-owners in several parts of England have to suffer is entirely due to the surreptitious importation of some dog which at the time was in the incubation stage of the disease. All Continental countries, with the exception of Norway, Sweden, and Denmark, are infected. Although mainly seen in the dog, rabies is also met with in the horse, cow, sheep, cat, fox, wolf, and even the fowl; in some of these animals the train of symptoms it produces is rather curious, and may not arouse any suspicion of the disease in the mind of the layman. Everyone knows something about the suspicious signs in the dog, although the classical symptoms are by no means constant. The change of manner, the desire to hide in dark corners, great excitability towards strange people and strange dogs, restlessness and weariness, snapping at imaginary flies, the attempts to chew and futile attempts to swallow all objects near at hand, the inability to swallow water, the continual salivation, and the final violent rage in the mad form—or the typically dropped jaw in the paralytic form—are all characteristic of the rabid dog. It is strange, too, what long distances the dogs will cover in their unconscious frenzy, wandering aimlessly on for miles; and it is for this reason that sometimes a large area or district has to be placed under the restrictions of the Ministry of Agriculture. The voice becomes altered, the bark being hoarse and accompanied by a most peculiar howl, the sound of which, when once heard, is never forgotten. Paralysis of the hind quarters and complete exhaustion and coma finally close the scene if the disease is allowed to terminate the animal's existence.

In the cat the symptoms are even more violent, and a rabid cat is even more to be feared by man than a rabid dog. It will bite and scratch, attacking men and animals in a most reckless fashion. The voice changes in tone, and eventually paralysis of the hind quarters comes. In the horse and ox there is violent excitement, and a particular symptom which has been noted again and again is an attempt to bite or rub the scar of the original site of infection, practically always the bite of a rabid animal. Sexual excitement is often present. Paralysis of the hind quarters is the common sequel, and the disease is always fatal.

The annual report of the Chief Veterinary Officer of the Ministry of Agriculture for 1919 showed that 143 cases of rabies were confirmed in that year (140 dogs, 2 horses and one pig). The first case was imported into Plymouth somewhere about May, 1918, and it is to this piece of criminal thoughtlessness on the part of someone that we owe the fact that we are now again an infected country. During 1919 alone some 179 persons were bitten by animals in the scheduled areas; of these, 46 were bitten by animals proved to be rabid. Treatment was arranged by the medical officer of the Ministry of Health, and it is a triumph to the memory of Pasteur that there have been no deaths from hydrophobia.

By the present arrangements the neck and head of any dog which has died or been killed as a rabies suspect is dispatched at once to the veterinary laboratory of the Ministry of Agriculture, together with a history from the field veterinary inspector who made the *post-mortem* examination. This is then dealt with at once, Negri bodies are searched for, and, if necessary, inoculation experiments are made; in 95 per cent. of cases a decision could be given at once, thus saving those patients who had been bitten much suspense and anxiety, and enabling the medical officer when necessary to advise immediate anti-rabies treatment. The necessity for the Muzzling Order still exists in certain areas, and both medical and veterinary

practitioners must be on the look out for rabies. But there is no doubt that what has been done before can be done again, and by ridding our island of rabies amongst animals the veterinarian will again render signal aid to his medical brother.

Foot and Mouth Disease.

Foot-and-mouth disease is not of quite the same importance, as a disease communicable from animals to man, as those previously alluded to, if neglected, however, it would cause a certain amount of trouble in human beings through the ingestion of the milk. This is not at all uncommon in countries where foot and mouth disease is indigenous, and I am told of at least one definite case of contagion in England to-day—an official who was constantly examining mouths and feet. Foot and mouth infection comes only from infected cattle, but it may be transmitted to the sheep, goat, and pig, and horses and even fowls are not immune.

In most European countries it is always present, and it is owing to our insular position and the precautions taken by the Ministry of Agriculture that we have kept so free in the past. This country was entirely free from 1895 to 1899, and again from 1903 to 1908, with the exception of two small outbreaks which were easily suppressed. The origin of the present outbreak is very obscure; as the virus is an invisible organism and the disease one of the most insidious and contagious with which we have ever had to deal, its control has presented many difficulties. Had not the outbreak been taken firmly in hand at once it is certain that it would have cost the agriculturist millions of pounds. As an indication of the extent to which it will spread it may be mentioned that in 1892 in Germany no fewer than 1,504,293 cattle, 2,193,157 sheep, 17,782 goats, and 438,262 pigs were affected, in other countries of the Continent it raged with equal violence. Even so recently as the spring of 1919 the north of Italy was visited by a terribly virulent form of the disease, and a great many of the agriculturists of the provinces of Milan, Turin, Tuscany, and Ciemona were ruined in consequence, as it affected not only the milking cattle but also the working bullocks.

Mange

Three mange parasites are found on the horse—a sarcopt, a psoropt, and a symbiote—but it is the two former which give trouble, man may be infected from contact with mangy horses, their grooming tools, feed utensils, etc., the infection usually occurs on the chest (especially if a hairy man) and the under surface of the forearm and on the hands. Riding a mangy horse has been known to infect men down the inside of the legs and in the pubic region, and during the late war this happened on numerous occasions, knackermen are frequently infected when employed in skinning mangy horses. Sarcoptic mange is very troublesome to get rid of in the horse, treatment takes several months. The psoroptic variety is much more amenable to treatment. Sulphur, in some form or other, forms the basis of most treatments. Measures had to be taken during the war for dealing with extensive outbreaks of the disease where large bodies of army horses were concerned. In Great Britain it is a notifiable disease.

That mange in the dog and cat is transmissible to man does not seem so generally known as it ought to be; some time ago Dr. Whitfield and myself published the histories of some seventeen cases in which he confirmed the existence of the sarcoptic parasite in the human subject, and I confirmed it in the dog. When treating dogs it is not uncommon to find the owner of a mangy dog complaining of irritation of the skin, usually on the inside of the forearm, where the little dog rests its head when being nursed. The contact of the warm skin causes the mange parasite to leave its original host. In some of these seventeen instances the infection had taken place in the region of the neck and chest owing to the objectionable habit of allowing the little dog to sleep in that situation, and one lady was infected on the abdomen. The lesions produced were described by Dr. Whitfield as small discrete vesicles, slightly smaller than the ordinary eczema vesicle and surrounded by a narrow zone of hyperaemia, very like that of varicella, only about one eighth of the size. The intense irritation leads to the decapitation of the little vesicles, and their original site becomes covered with either a serous or a blood scab. If left untreated the parasite will live in the human subject for about six weeks, but if treated is readily got rid of. In the dog we

have two varieties of parasite, the *Sarcoptes canis* and the *Demodex folliculorum*; both are infectious to man, and the latter gives the veterinarian endless trouble to cure. Sarcoptic mange yields readily to treatment, but it takes about a month or six weeks to effect a certain cure. If neglected the dog becomes covered with scabs and sores, gets thin and emaciated, has a peculiar mousy odour, and will eventually die. The cat suffers from sarcoptic mange, which reduces the animal to a loathsome and miserable condition. The uncastrated male cat is, in all large towns, a fruitful source of the spread of sarcoptic mange amongst the females, and indeed to other males with whom he is constantly at war.

Ringworm.

All ringworm of the horse, calf, dog, and cat are contagious and give considerable trouble in their treatment. In country districts the calf is the constant source of infection, and in town generally the cat. Dr. Whitfield and others have recorded several cases of infection from animal to man.

Tuberculosis.

Professor Hobday dismissed tuberculosis briefly, the subject being, he said, so large as to call for a separate discussion. Before the war the subject of a clean milk supply and the eradication of tuberculosis from herds was being taken up with vigour; the work must be resumed; it was deplorable that at present milk inspection should so often be merely perfunctory.

THE MENTAL AFTER-CARE ASSOCIATION.

THE annual meeting of the Mental After care Association, which has done much valuable work during the last forty years in aiding the restoration to ordinary mundane activities of large numbers of poor persons discharged convalescent or recovered after treatment in mental hospitals, was held on February 24th at Brixton Royal Hospital. Alderman Sir Charles Wakefield, Bt., who presided, after giving examples of the beneficent results of the Association's operations with the very limited funds at its disposal, announced his generous intention to defray the deficit of £70 outstanding at the end of last year. The report was read by Dr. Henry Kayner (Chairman of the Council), and its adoption moved by the Right Hon. Sir William Byrne, Bt., Chairman of the Board of Control, who drew attention to the great value of the timely help and assistance, on discharge, of necessitous patients in consolidating recovery and preventing relapse, incidentally referring to the high character of the services of the staffs of our asylums, sometimes ungraciously impugned by certain irresponsible sections of the press. The motion was seconded by the Bishop of Barking and carried. The re-election of the officers was proposed by another member of the Board of Control, Dr. Hubert Bond, C.B.E., and seconded by the Hon. John Mansfield (Lord Chancellor's Visitor), and the adoption of the balance sheet, which showed an aggregate income for 1920 of £3,061 15s 8d. (more than half of which was derived from charitable sources), was moved by Mr. Gabain and seconded by Sir George Savage, M.D., Treasurer of the Association. A hearty vote of thanks to Sir Charles Wakefield for presiding and for his generous donation, closed the proceedings.

The following statement of the methods adopted by the Association may give an idea of its varied activities. It facilitates rehabilitation into ordinary social life of suitable cases as follows:

1. By friendly visits, sympathy, and advice (if desired), and by keeping in touch with them as long as they need help in any way.
2. By boarding them out, when thought desirable, for a few weeks with families in the country, under proper care (in cottage homes).
3. By placing them in various institutions in London and other large towns until work can be found.
4. By finding them suitable employment.
5. By giving them grants in kind or in money towards maintenance while seeking work, by providing clothing, by redeeming or procuring tools when occupation is found.

The offices of the Association are at Church House, Dean's Yard, Westminster, and the Secretary is Miss E. D. Vickers.

British Medical Journal.

SATURDAY, MARCH 5TH, 1921.

PUERPERAL MORTALITY IN 1919.

It is a disheartening and almost humiliating discovery to find by the Registrar-General's report that puerperal mortality in England and Wales, both as a whole and as regards puerperal sepsis separately, was greater in 1919 than in any year since 1905.

The number of deaths assigned to pregnancy and childbirth in 1919 was 3,028, corresponding to a rate of 4.37 per 1,000 births, but in order to compare with causes of death under the classification in use up to 1910, 176 deaths allocated to "puerperal nephritis and albuminuria," formerly not distinguished as puerperal, are deducted. This brings the 1919 mortality rate down to 4.12 per 1,000 births, as against an average rate of 3.74 in the ten years immediately preceding.

Unfortunately the Registrar-General finds that "the increase in 1919 is preponderantly due to septic disease," which is very difficult to explain considering the efforts which have been made to educate both medical students and pupil midwives on the need for surgical asepsis in midwifery. The mortality due to sepsis, including phlegmasia alba dolens, in 1919 was 1.76 per 1,000 births, the highest rate since 1905, when it was 1.87. This is particularly disturbing when it is remembered that in 1918 the mortality rate, both from all causes (3.55) and from "sepsis" separately (1.35) per 1,000 births, was the lowest on record, except that in the one year 1913 the deaths from sepsis were 1.34 per 1,000 births.

It would seem that our present methods for preventing puerperal infection are still insufficient. Over seventy years ago (1847) Semmelweis, then an assistant at the Vienna Lying-in Hospital, began an inquiry into the cause of the 10 per cent. puerperal mortality of his hospital patients as compared with those attended at their own homes, and came to the conclusion that the morbid process was a wound infection due to the introduction of septic material by the examining finger. The mortality fell to 1 per cent. after he insisted upon hands being disinfected with chlorine water; but his views were not appreciated, nor were they adopted either here or elsewhere. In 1873 Lister initiated antiseptic methods in surgery, but it was not then realized that the principle should be applied to midwifery. In 1865 Mayrhofer discovered that streptococci were often present in the tissues of women who had died from puerperal fever. In 1872 the Obstetrical Society of London appointed a strong standing committee to "collect evidence on temperature during pregnancy, parturition, and the puerperal state." Its object was to show how puerperal fever might be prevented, and special efforts were made to get midwives properly trained.

In 1905 the Central Midwives Board took over the Society's examination work, and under the able chairmanship of Sir Francis Champneys excellent work has been done; some reduction in the deaths due to puerperal septicaemia ensued, for the death rate from this cause, which had never been less than 2 per 1,000 births (except in 1898, 1.91), gradually fell to 1.42 in 1910 and 1.34 in 1913. More than this

had been expected from compulsory education, examination and registration of midwives, but the necessity of putting 12,521 untrained women, practising as midwives, upon the roll no doubt vitiated the result.

In 1880 Pasteur cultivated streptococci from cases of puerperal fever, and it gradually dawned upon civilization that the mortality was due to infection. Other germs, such as staphylococci and the *Bacillus coli communis*, are sometimes infective agents, but are usually found in combination with streptococci. Dr. Victor Bonney's contention that puerperal sepsis is largely due to infection by the bowel organisms from the patient herself, owing to the parturition and defaecation areas being so closely adjacent, must not be forgotten in this connexion, but it is difficult to accept his statement that "Nature has made the mistake of placing the birth area almost in the middle of this danger zone."

The Registrar-General divides deaths of women in pregnancy and childbirth into two large groups. The first contains 3,028 deaths classed as due to pregnancy and childbirth, and includes deaths from puerperal sepsis and from "other accidents of childbirth." The second group consists of 1,337 deaths of women not classed as due to pregnancy or childbirth, but "associated therewith." The first group consists of (a) conditions which, if detected during pregnancy, could be so dealt with, then or at a later date in the pregnancy, that maternal deaths would very rarely occur. Amongst these may be named (with deaths in brackets) contracted pelvis (47), craniotomy (9), malpresentation (12), hydatid mole (6), retroversion of the gravid uterus (6). (b) Cases many of which probably died for want of prompt or expert treatment, in sudden or unexpected "accidents" of pregnancy or childbirth, such as abortions (121), some probably criminal, ectopic gestation (73), placenta praevia (169), haemorrhage of pregnancy (43), rupture of uterus (20), inversion of uterus (8), inertia uteri (7), abnormal foetus (9), difficult or prolonged labour (44). (c) Deaths due to toxæmia of pregnancy. These are not grouped under that head, but separately, such as uncontrollable vomiting (28), puerperal nephritis and uræmia (131), puerperal albuminuria and Bright's disease (44), puerperal convulsions (420). Many of these cases might have been saved if detected in the early stages of toxæmia by routine urine analysis. (d) Deaths from puerperal fever, including those from phlegmasia alba dolens (51), numbered 1,208. Probably some of the deaths from "puerperal embolism and sudden death" (179) may have been infected cases.

Nearly all these deaths from "puerperal fever" (or as they should now be termed "puerperal infection") should be preventable, for true autogenetic cases are very rare. It would seem that the doctor or midwife concerned must deal with parturition as a surgical process, avoiding all unnecessary contact with the maternal tissues and all rough usage where contact is required; the tissues involved in the birth exit and the areas around must be treated as he would the tissues round a proposed vagino-perineal plastic operation. The modern doctrine is that the accoucheur must wear recently boiled rubber gloves and a sterilized overall on every occasion when examination is necessary. He must recognize early in labour the conditions likely to lead to delay or complication and arrange for the necessary assistance. He and his assistants must be free from dental caries, ozaena, etc., and from all other sources of infection. These aseptic precautions are now taken in all maternity wards and hospitals, and puerperal epidemics do not now occur.

The question arises, therefore, why there is not equal freedom from puerperal infection outside hospital clinics. Most of the midwifery (probably 70 per cent.) of the country is in the hands of midwives, and they ought to be in touch with qualified practitioners. Midwives are now well instructed, and their work is carefully inspected and supervised. Many writers, including teachers of obstetrics in every school of medicine, have repeatedly drawn attention to the subject during recent years. They have discussed the prevention of infection and better education in practical midwifery, so that students may be prepared not only to anticipate complications by ante-natal supervision, but be able to deal with them effectively when they arise. To do this, it is maintained, the student must have seen women delivered by experts in special lying-in wards which are equipped as fully as operation theatres for all emergencies, and must have seen all the minor operations of version, forceps, etc., performed by skilled teachers and have had some opportunities for personal experience.

Every general practitioner practising midwifery should be an expert. Obstetrics is not a speciality which can be in the hands of a few, like some other specialities, for at any moment the accoucheur, perhaps soon after being qualified, may be called upon to deal with a sudden emergency during pregnancy, childbirth, or the puerperium; such a case will not be met by a consultation in a few days' time; it must be dealt with at once. It is almost impossible with the present supply of maternity beds to enable this experience to be gained during a student's curriculum. This is perhaps more particularly true of London. Every general hospital should have a maternity ward or be associated with a lying-in hospital.

Even if a doctor has had special midwifery training, he—and perhaps still more the midwife—is seriously handicapped, both as regards sepsis and space, by the conditions of the rooms where women are confined in poor and middle class practices. Dr. Victor Bonney's graphic word picture of such a bedroom loaded with furniture and oddments is not exaggerated, and the difficulty of its conversion into an aseptic lying-in room is not overstated. Yet there is at present no possibility of getting all parturient women, or even all primigravidae, into a local cottage hospital or maternity ward.

If ante-natal supervision were universally adopted, and complications anticipated, and if there were a more definite linking up of patient with midwife, doctor and hospital, the incidence not only of infection but of all other accidents of pregnancy and childbirth would be greatly diminished, and puerperal mortality and morbidity would continue to decrease.

The second large group of 1,337 deaths are those "not classed as due to pregnancy and child-bearing, but returned as associated therewith." Inclusion of these deaths raises the proportion of deaths caused by or associated with pregnancy and childbirth to 6.3 deaths per 1,000 births. These deaths may be divided into two smaller classes. The first class contains deaths due to conditions, usually acute, which do not arise from, but complicate, the pregnancy or childbirth, such as influenza (585), lobar pneumonia (76), bronchopneumonia (34), scarlet fever (10), appendicitis (10), intestinal obstruction (10), acute phthisis (13), enteric (3). Some of these influenzal deaths may have been cases of puerperal infection: the distinction is sometimes very difficult. The second class consists of deaths due to the association of pregnancy or childbirth with pre-existing, usually chronic, pathological states, such as heart disease (177), pulmonary tuberculosis (66), Bright's disease (37), anaemia (21), epilepsy (8),

syphilis (7), cancer (6), diabetes (6). Cases in both classes, if in hospital, would be usefully seen by experts in both obstetrics and in medicine or surgery as indicated by the particular complication present.

THE PANDEMIC OF INFLUENZA, 1918-19.

THE Ministry of Health has come in for a great deal of criticism in the lay press, some of it undeserved and apparently due to political considerations; some it brought on itself. We warned the Ministry from the first that the introduction of its Miscellaneous Bill was a mistake, for reasons now apparent. But the medical profession looks to the Ministry for much more than legislation. In fact, legislation is only an incidental function; its important duties are the review of administrative effort in the light of increasing knowledge, and the collection and dissemination of information, especially with regard to epidemics. An excellent illustration of the intelligence work the Ministry of Health can do is afforded by the recent report on the pandemic of influenza 1918-19.¹

This intensive study of a devastating historical epidemic in all its aspects is summarized in a philosophic introduction by the chief medical officer, Sir George Newman, who again emphasizes the unitary character of the problems of health and disease, and points out that the only sure defence against sudden and terrible epidemics is to raise the whole standard of life not only in this country but in all countries. The report is especially rich in its epidemiological aspects, which are dealt with in an article published at p. 348; the clinical section contributed by Dr. Herbert French will appeal very directly to the medical practitioner; it covers familiar ground and its conclusions can be tested by the results of his own experience.

The pandemic consisted of a first wave in June, 1918, of a comparatively mild character—"the influenza of the three-day fever type"—with sudden onset and fever running up to 103° or 104° F., and a rapid convalescence, so that the great majority of the patients were fit for work by the end of a week; there was little tendency to complications, and only those disposed to bronchial catarrh by chronic bronchitis or emphysema suffered from pulmonary infection. Very different was the second wave in the autumn with a recrudescence in February, 1919, for though the general type of cases was much the same as in the first wave, there was a tendency to severe and fatal pulmonary complications. Broadly speaking, it is estimated that out of 1,000 persons attacked during the second wave fully 800 had an ordinary attack of uncomplicated influenza, very commonly with epistaxis, and perhaps rather more severe than the three-day fever of June, 1918; the remaining 200 were severely ill with pulmonary complications, and of these about 80 (or 40 per cent.) died. This may also be illustrated by Sir Robert Hill's² figures from the Royal Navy, where the first wave was accompanied by 0.4 per cent. of complications and 0.03 per cent. mortality, whereas in the autumn wave the incidence of complications was 6.8 per cent., and of deaths 2.8 per cent. The explanation tentatively suggested by Dr. French for this remarkable seasonal change of type is that whereas the *Bacillus influenzae* alone may be responsible for the 800 mild cases, one or more

passed by the Pharmacopoeia Committee authorizing the President of the General Medical Council "to approach the Government with a suggestion for the establishment of a public institution for the pharmacological standardization of potent drugs and of serums." The Government were approached accordingly, but it was not found possible to take immediate steps in the direction indicated, and it became evident that nothing could be done in time for a fresh edition of the *Pharmacopoeia*, which ought to have been published in 1912, but did not appear until 1914. Standardization of such substances as vaccines, serums, antitoxins, and analogous products, is left at present wholly to the private enterprise of manufacturers, and each maker is free to adopt his own conception of adequate standards. Hence any guarantee of potency and authenticity entirely depends upon the reputation of the supplying firm. The reputation of the British manufacturers of these substances is deservedly high, but there are obvious disadvantages attaching to the present state of affairs, especially as these products may be imported into this country without check or guarantee of any kind. Manufacturers have perforce had to adopt foreign standards to which reference can be made in cases where biological assay is necessary, as there are no British standards in existence. Accordingly, in April, 1920, the Minister of Health appointed a committee to consider and advise upon the legislative and administrative measures to be taken for the effective control of the quality and authenticity of such therapeutic substances as cannot be tested adequately by direct chemical means. The substances included may be classified into: (a) a group comprising the bodies conveniently described in the United States Regulations of 1919 as "biologic products"—that is, vaccines, antitoxins and the like; (b) a group of potent synthetic remedies, such as salvarsan and its analogues; (c) a group corresponding more nearly with the ordinary definition of "drugs"—for example, digitalis, strophanthus, ergot, cannabis indica, and pituitary gland. Most of the substances in the last group are included in the *British Pharmacopoeia*, and certain primitive tests and methods of identification are therein provided for them, but there is a considerable volume of opinion that these tests are far from adequate as standards of therapeutic efficiency, and although the application of physiological standards to substances in this group is hardly of the same importance as in the two former groups, such standards would be accessory guarantees of efficiency. The Committee examined a large number of witnesses representing not only scientific bodies, but also firms actually engaged in the manufacture and sale in this country of the substance under consideration. As the result of the investigations the Committee's report, which is now published,¹ recommends that therapeutic substances which cannot be tested adequately by chemical means should be subject to supervision and control under the authority of a committee of the Privy Council assisted by an advisory committee. There should be a central laboratory under Government control, wherein standards would be prepared and maintained, research on the subject carried out, and tests made to ascertain that the products issued by manufacturers conform with the standards laid down. It is recommended that the Medical Research Council, which already possesses the requisite organization, should be responsible for this central laboratory. The method of control should include the licensing of manufacturers, inspection of their plant, premises, and processes, and the testing of the finished products, preferably from samples taken from makers' stocks or bought in the open market, leaving to the manufacturers the primary responsibility for securing that the products conform with the prescribed standards. Products made abroad should be subject to restrictions similar to those applying to products made in the United

Kingdom, and licences should be granted to approved manufacturers, while in addition steps should be taken to ensure that each consignment imported attains the standards laid down for similar products of home manufacturers.

DISABLED SOLDIERS AND THE DIAMOND INDUSTRY.

In view of the importance of the question of employment for disabled soldiers, the work that is being done at the Bernard Oppenheimer Diamond Works is of interest. These consist of a series of fine buildings at Brighton, capable of holding 2,000 workmen, and of subsidiary branches at Cambridge, Fort William, and Wrexham, which can train 250 additional men. The industry is a new one in England, and the work is being carried out practically in its entirety by disabled men. Nearly half of the men are suffering from disability due to amputations, while the disabilities of the majority of the others are due to gunshot wounds, either of the shoulder and arms, or of the thigh and legs. The undertaking has passed the experimental stage, and is now on a sound financial basis. Much credit is due to Sir Bernard Oppenheimer for the risk he undertook in staking, not only his reputation as a successful diamond merchant, but also the large outlay in capital which was necessary. Credit is due also to the Ministry of Pensions and the Ministry of Labour for their co-operation in endeavouring to smooth over many difficulties which at first must have been almost insurmountable. At the time of the establishment of the first wing of the factory the greatest difficulty and inconvenience was found in carrying on concurrently the training and at the same time the necessary medical treatment of the men. It was necessary for them to attend at a hospital or private clinic, sometimes daily or twice daily, at hours which were invariably the regular working hours, with the result that each treatment meant the loss of half a day's work. As there were occasions when 25 per cent. of the employees were absent undergoing treatment, it was manifestly impossible to train men under these conditions, and with the approval of the Ministry of Pensions a clinic was established on the premises. The clinic consists of one room for massage and electrotherapy, one for remedial exercises, one for x rays and high-frequency and diathermy apparatus, one room as a surgery, a waiting-room, a room for the medical referee, and another for the works doctor. The saving of time by having the clinic on the spot is enormous; there is no waste, as each man has his definite hour for treatment or comes when sent for by the orderly. On an average 60 to 70 pensioner-employees receive massage, electrical, remedial, or combined treatment every day. The results have been very satisfactory, and some twenty patients are discharged each month, benefited or cured, while in the surgery twenty cases on the average are dressed every day—for discharging sinuses, stump infections, or other conditions due to war service. The kind of treatment and its duration are left entirely in the hands of the medical referee, Colonel Langmuir Watt, C.M.G., and there is no attempt to carry on treatment for conditions other than those due to war service, except first aid in the case of accidents. The clinic has also been made a limb fitting centre; a stock of the more perishable parts of artificial limbs is kept in the clinic and issued as required, and there is little or no delay, as minor repairs take only a few hours, and more serious repairs never longer than from one to two weeks. New limbs are obtained as rapidly as if the men were at Rochester. The great problem still to be solved, Colonel Langmuir Watt tells us, is the provision of a working limb—as distinct from a walking limb—which can permit of its wearer sitting down for four hours at a stretch without causing pain or discomfort, or overheating of the stump. A hut adjoining the works has just been erected by the British Red Cross Society and the Order of St. John of Jerusalem, where they will be

¹ Report of the Departmental Committee on Control of Certain Therapeutic Substances, H.M. Stationery Office. 1921. Price 2d. net.

able to carry on satisfactorily the fitting and manufacture of peg legs, surgical appliances and surgical boots. Arm amputations are not very suitable for the work, but even these cases have been successfully trained, some fitted with a special mechanical appliance invented in the works, while there are many men with more or less useless arms, due to such conditions as ankylosis or paralysis, earning average wages. The actual work of diamond polishing is naturally very exacting, and the men must possess good eyesight, sound nervous systems, and intelligence rather above the average. All applicants for training have to undergo a careful practical test of their fitness; this is of benefit not only to the Ministry of Labour, but also to the works, as it tends to prevent men from being released after a few days' trial with the necessity of finding a new training for them. Canteens and a recreation room have been provided for the men. Their period of training is eighteen months, though actually after six months of works attendance a man is supposed to be able to earn his living. During these six months the sum of £2 a week is paid by the Ministry of Labour, at the end of that period a man goes on works pay, the minimum being £2 a week—of course entirely independent of his pension—from which he may rapidly rise, as many of the men have done, to £5 or £7 weekly. Medical practitioners who are interested in this subject are invited to visit the works.

DECEREBRATE RIGIDITY IN MAN.

It has been thought and even stated in some quarters of recent years that medicine can expect to learn little more from purely clinical observations. Neurology, however, is fortunate in being a branch of medicine in which original clinical observations continue to lead to great increase in our knowledge of the functions of the central nervous system as a whole. And we are proud to be able to say that in this field British neurology can fairly claim a prominent place. Dr. Kinnier Wilson's¹ recent contribution is a shining example, if such were needed, of the value of careful and prolonged clinical study of symptoms which, though familiar to many, have hitherto eluded satisfactory explanation. He has drawn a luminous comparison between the experimental decerebrate rigidity of animals (following transection of the brain stem through the mesencephalon) and certain cases in man "in which there is evidence of withdrawal of cortical control in the form of unconsciousness or semiconsciousness coupled with the appearance of tonic rigidity of the trunk or limbs, with exacerbations in the form of tonic or postural fits." The first group of cases quoted are examples of decerebrate rigidity combined with tonic fits, and pathologically comprised a tumour of the frontal lobe with haemorrhage into the ventricles, a tumour of the mesencephalon, general septic meningitis with some internal hydrocephalus, a case of cerebral haemorrhage with extension into the ventricular systems of the brain, and a case of tuberculous meningitis with moderate internal hydrocephalus. The description of these cases is very full and vivid, and the author points out how the tonic posture was maintained, while the actual fits were an accentuation, so to say, of the already existing decerebrate position. The absence of any clonic element in the fits is emphasized. Tonic or "cerebellar" fits, as they were originally called, may occur without the maintenance of the decerebrate posture, and a very striking example of such a condition is given in full. Their association with hysteria is also pointed out, the position of opisthotonus with extension of the legs and extension and pronation of the arms being a well recognized phenomenon. Of particular clinical interest are those cases which exhibit a unilateral or fragmentary decerebrate attitude in one limb only. The so-called decerebrate attitude of the head may be thus explained. The extreme pronation of the

hand which is found, for example, in athetosis or chorea is held by the author to be but a fragment of the complete picture of the decerebrate posture. In explaining the pathogenesis of this condition tribute is paid to the theory of "cerebellar influx" propounded as long ago as 1877 by Hughlings Jackson. The numerous experimental researches of Sherrington, Graham Brown, Weed and others, however, point to the conclusion that the mesencephalon is the principal site responsible for the maintenance of the decerebrate posture; and the red nucleus is credited with particularly important functions in this respect. We are promised a further study on the part played by the basal ganglia in the regulations of these functions. No student of neurology can afford to miss this communication, to which a full bibliography is attached; and further contributions will be awaited with interest.

THE RETARDED CINEMA.

Last week Dr. Gustave Monod-Walter gave a demonstration at the house of the Royal Society of Medicine on the cinematograph, which excited so much interest that he consented to repeat it this week. The films were taken at the rate of about 300 pictures to the second, slowed down when exhibited to perhaps fifteen or twenty in a second. In this way every detail of movement can be observed, and it has been hoped—a hope not yet realized—that the method would be of value in the study of movement. The first film was of a type fairly familiar in this country—jumping and putting the shot; and the second, of the isolated mammalian heart, showed in a film what most British students of to-day have seen in the laboratory. The last film, taken at the Institut Marey, Paris, was an analysis of the drive, approach and putt as performed by the French golf professionals Lafayette and Botcazou—the latter one-armed; this film excited, it must be confessed, a good deal more interest than the others, partly, perhaps, because of its novelty, but partly because the majority of the audience appeared to be golfers. A study of it may perhaps help the inexperienced player or he who is off his game; but we are inclined to agree that the object to be attained rather than the means of attaining it should be had in mind, or, as Dr. Monod-Walter said, the player should trust to his imagination rather than to his will.

MEDICAL SCHOLARSHIPS FOR SERBIAN GIRLS.

A drawing-room meeting was held on February 10th at 28, Kensington Court, by kind invitation of the Lady Swaythling, in aid of a scheme for raising a fund to endow one or more scholarships for Serbian girls in connexion with the London School of Medicine for Women and the Royal Free Hospital. The successful candidates will be required to undertake to return to practise in their own country when qualified. The speakers were Sir Willoughby Dickinson, Dr. Mary Scharlieb (chairman of the fund), Dr. Dickinson Berry (the honorary secretary), and Mrs. Carrington Wilde. The scheme was recommended as a fitting memorial to the work of medical women in Serbia and as a means of helping to maintain the cordial feelings between Serbians and Britons produced by intercourse during the war. The outlook of Serbian women, it was stated, has enlarged greatly since the beginning of the war. There is a keen desire among them for higher education, and especially for a medical career, which many have already taken up. To study in England is said to be the highest ambition of every Serbian student, male or female. Sir Willoughby Dickinson drew attention to the value of scholarships in drawing nations together and teaching people of various nationalities to know one another—factors of the greatest importance in the future peace of the world. Mr. Garrilovitch, the Serbo-Croat-Slovene Minister, supported the scheme and proposed a vote of thanks to Lady Swaythling for holding and presiding at the meeting.

¹ S. A. Kinnier Wilson, *Brain*, vol. XLII, Part III, 1922.

The centenary of the death of Keats was celebrated at Hampstead by a pilgrimage to various places more or less directly associated with his residence there, and in Rome by a visit to the English cemetery. Keats took the diploma of Licentiate of the Society of Apothecaries on July 25th, 1816. There hang in the Court Room of the Apothecaries' Hall his portrait, and an original abstract from the candidates' entry book giving particulars of his apprenticeship, attendance at lectures, and hospital practice. Keats was a student at Guy's Hospital, and for part of the period that he was attending there lived in lodgings at Bird-in-Hand Court, Cheapside.

LORD MILNER'S Fund for the London School of Tropical Medicine now amounts to £117,000. The school obtained its new buildings, including a hospital, in Endsleigh Gardens, by means of a gift of £100,000 from the Red Cross Society. Lord Milner's Fund, which it is hoped will reach £150,000, is to provide for the maintenance of the school and for research. It was in 1899 that Lord Milner's great predecessor as Colonial Secretary, the late Mr. Joseph Chamberlain, made his appeal to the public for a capital sum to establish the school.

We regret to announce the death, in his 92nd year, of Sir Charles A. Cameron, M.D., who for many years had been chief medical officer of health and public analyst for the city of Dublin.

Medical Notes in Parliament.

Dangerous Drugs Regulations.

MR. CLOUGH asked the Home Secretary, on February 24th, what was the result of the submission of the preliminary draft of the Regulations under the Dangerous Drugs Act by the Home Office to the Pharmaceutical Society of Great Britain, the Pharmaceutical Society of Ireland, the General Medical Council, the Royal College of Physicians, and the Royal College of Surgeons; whether, prior to the publication of the draft Regulations by the Home Office any, and if so which, of those bodies had indicated their approval of the draft; and whether any, and if so which, had submitted objections. Mr. Shortt said the result of the communication of the preliminary draft in November last to the bodies mentioned for their observations was as follows: The Royal College of Physicians and the Royal College of Surgeons considered the draft satisfactory and offered no observations, except that the Royal College of Physicians thought the minimum limit in the case of cocaine (which is fixed by the Act and cannot be altered by Regulation) too high. The General Medical Council also approved the Regulations, but asked that the directors of research laboratories might be included among the classes of persons who are authorized by the Regulations themselves to be in possession of the drugs. The Pharmaceutical Society of Great Britain replied by a letter maintaining that the proposal in the Regulations to prohibit the sale of drugs to the public except on a medical prescription was *ultra vires* of the Act, and proposing that before going on with the Regulations the Government should appoint a Committee to consider the desirability of separating the functions of prescribing and dispensing. The reply of the Pharmaceutical Society of Ireland, which was not received till after the draft had been published, submitted objections on various points.

Indian Medical Service.—Mr. Gwynne asked, on February 23rd, whether the Secretary for India was aware that the Indian Medical Service had received neither the benefits of the accelerated cadre promotion granted in the British Army and the Royal Army Medical Corps nor the accelerated time promotion granted in the Indian Army; whether the reason given for the exclusion of the Indian Medical Service from the British Army and Royal Army Medical Corps cadre acceleration to field lieutenant-colonelcy was because the Indian Army did not have it, and from the Indian Army time scale acceleration to field rank because the Royal Army Medical Corps did not have it. Mr. Montagu said that he found some difficulty in understanding the question, and asked for particulars of any specific case on which it was based. He offered assurance that there had been no discrimination against the Indian Medical Service.

The Spahlinger Treatment for Consumption.—Asked by Mr. Lynn, on February 23rd, for information regarding the Spahlinger treatment for consumption, Dr. Addison said he had made full inquiries regarding this supposed remedy for tuberculosis, but it was clear that much further investigation and experience would be necessary before accepting the claims made for it. It appeared that as long ago as 1913-14 the serum in question was prepared. It was tried by several hospital physicians, but there was not yet sufficient evidence of its therapeutic value, nor had the trials been sufficiently extensive to justify any definite and reliable conclusions. He understood that a supply of serum was not likely to be available for some months, and that on account of the secrecy maintained as to its constitution and method of preparation, it had hitherto been found impossible for the recognized research laboratories in this country to investigate its effects.

Industrial Fatigue Research Board.—Captain Elliot asked, on February 24th, whether the Treasury had ordered the Industrial Fatigue Research Board to be wound up by March; whether this body had recently issued a most valuable report on conditions in the steel making industry, indicating methods for securing greater efficiency in production; and whether it was the case that the dissolution of this body now would mean the loss of all the work and money spent in getting it to the present point, when it was beginning to show a return. Dr. Addison replied that the matter was under consideration, and he hoped soon to be able to give definite reply. The Government entirely shared his views as to the report in question.

Salaries at the Ministry of Health.—Sir T. Polson asked the Chancellor of the Exchequer, on February 23rd, whether the salary of the First Secretary of the Ministry of Health had recently been increased from £2,000 to £3,000 per annum, and that of the Second Secretary from £1,700 to £2,000, and on what grounds these increases had been made. Mr. Chamberlain replied that the salary of the First Secretary to the Ministry of Health had been increased from £2,000, plus £750 bonus, to £3,000, plus £500 bonus, and that of the Second Secretary from £1,700, plus £750 bonus, to £2,200, plus £500 bonus, in pursuance of the recommendation of a committee appointed by the Government to advise them as to the emoluments which should attach to the principal permanent posts in the Civil Service. Mr. Asquith had acted as Chairman of the Committee.

Medical Records.—Sir Douglas Hall asked, on February 24th, whether the earlier system of record cards of insured patients proved to be useless and were practically unexamined, large quantities of cards being sold as waste paper, and whether Dr. Addison anticipated a better fate for the new cards. Dr. Addison replied that the cards under the earlier system of record were by no means useless; they were sold only after having served their purpose; but their value for clinical purposes was gravely impaired because at the end of every year they were surrendered and the particulars as to the names of the patients and their illnesses separated. It was because of this inherent defect in the old cards that the new records had been designed by a committee mainly composed of members of the medical profession, who gave fuller place, and in his view rightly so—to the clinical object of the record, and so designed the form which might serve as a continued record of insured persons' illnesses. These records would undoubtedly be of great value, and the keeping of them would give less work than the old records. Sir D. Hall asked what was the position of a panel doctor who made an inaccurate statement regarding the diagnosis of a disease on the new record of an insured patient, whereby the patient was subsequently damaged; and whether, if the panel doctor was liable in such cases to pay damages, provision would be made to indemnify him in respect of an error in a document which he was compelled to compile under conditions which often rendered accuracy difficult or impossible. Dr. Addison said he did not understand what particular contingency Sir D. Hall had in mind, but he was advised that, in the absence of negligence on the part of the doctor, no liability for damages could arise in this connexion. Dr. McDonald had previously asked, on February 23rd, if, in order to obtain true health statistics for the nation, Dr. Addison purposed ultimately issuing record cards to the whole population, and not, as at present fore-cards to the whole population, and not, as at present fore-cards to the whole population, and not, as at present fore-cards to the whole population. Dr. Addison shadowed, limiting the issue to insured persons. Dr. Addison replied that he did not think it was practicable to give effect to the suggestion.

Insurance Doctors' Duties.—Mr. R. Young asked, on February 23rd, whether the attention of Dr. Addison had been drawn to the case at Old Street Police Court, where it was elicited that a panel patient had to pay 2s. 6d. for each visit she made to the doctor because she could not afford to leave her work to attend at the surgery during the hours fixed for panel patients. Dr. Addison said his attention had been called to the case, which, he learned, was under investigation by the London Insurance Committee.

National Insurance Contributions.—In answer to Mr. W. Thorne, Dr. Addison said, on February 23th, that an allowance for four weeks' unemployment and any weeks of sickness in each year was already made before an insured person was subject to any reduction of benefits for arrears under National Insurance; if the arrears exceeded this allowance, an opportunity was given to the insured person to make a comparatively trifling payment between July and November of each year in order to avoid any reduction of benefit. In these circumstances, Dr. Addison did not think it necessary to make any exceptional arrangements to meet the present distress.

Prison Medical Officers.—In answer to Mr. Stoh, on February 23rd, Mr. Shortt said there were thirty-one part-time medical officers employed at the following prisons: Bedford, Bristol, Canterbury, Cardiff, Carlisle, Carmarthen, Carnarvon, Dorchester, Durham, Exeter, Gloucester, Hull, Ipswich, Leicester, Lincoln, Maidstone, Newcastle, Northallerton, Northampton, Norwich, Nottingham, Oxford, Plymouth, Portsmouth, Preston, Shepton Mallet, Shrewsbury, Swansea, Usk, Winchester, and Worcester.

Disability Pensions.—Mr. Macpherson, replying to Mr. T. A. Lewis on February 23rd, said he was not prepared to accept the suggestion that any man who, entering the army in sound health, was discharged with impaired health would have his invalidity automatically attributed to military service. Each case was considered on its merits in the light of all available evidence; and if a claim for pension was rejected by the Pensions Ministry on the ground that the disability was not due to service, the man had a right of appeal to an independent tribunal.

Farmers and the Dangerous Drugs Act.—Mr. Shortt, in answer to Lieut.-Colonel Guinness, stated, on February 23rd, that he proposed to insert words in the Regulations expressly authorizing the supply of drugs for the purpose of the treatment of animals on the prescription of a veterinary surgeon. Further de aids as to the application of the Regulations to agriculture were under consideration in consultation with the representatives of the agricultural interest.

Tuberculous Ex-Service Men.—Dr. McDonald asked, on February 24th, if the Minister of Pensions would reconsider his attitude towards ex-service men who had been certified as suffering from tuberculosis shortly after their discharge from the army, on account of being unfit for further military service, and now considered ineligible for pension; whether he was aware that, while the health of some men was improved by service, the health of others had deteriorated, the way to tuberculosis being thus paved, and whether cases of this sort would be dealt with more sympathetically than men months after their discharge. Mr. Shortt replied that he was not aware that claims to pension on the ground of tuberculosis were unsympathetically considered. If the tuberculosis developed within a short period of discharge the disablement was generally admitted to be either attributable to or aggravated by service, and even where the disease did not develop until after a considerable period, the circumstances of the man's military service and of its effect on his health were carefully examined. If the Ministry were unable to accept his claim the man was advised of his right to appeal to an independent tribunal.

Delay in Appeal Tribunals.—Lieut.-Colonel Sir F. Hall asked a question, on February 24th, as to delay in hearing cases before the appeal tribunals, particularly in the London region. Mr. Macpherson replied that two extra courts were now sitting, and that two more would begin sitting on February 28th. The question of further increasing these courts was now under consideration by the Lord Chancellor. He had no control over the appeal tribunal, but would approach the Lord Chancellor to see whether more courts could not be provided, as there was reason to fear that there might be an increase next month in the number of cases awaiting hearing.

The Dentists Bill.—Dr. Addison stated, on February 23rd, that he was in a position to name any particular date for the introduction of the Dentists Bill, but if there were a general desire in the House that the bill should be introduced without delay, and if it would be treated substantially as an agreed bill, the Government would be prepared to introduce it in another place at an early date.

Sinking of Hospital Ships.—The Attorney-General, in reply to Mr. Bottomley and to Sir F. Hall, stated that the list of the names of forty-five Germans accused under Article 223 of the Treaty of Peace with Germany was handed on May 7th, 1920, to the German Government. To this list the British Government contributed the names of the following: the hospital ship *Lila*, the hospital ship *Patzig*, and the hospital ship *Patzig*, of which the latter was sunk on the 1st of May 1920.

The hospital ship *Lila* was sunk on the 1st of May 1920, and the hospital ship *Patzig* was sunk on the 1st of May 1920. The hospital ship *Patzig* was sunk on the 1st of May 1920, and the hospital ship *Lila* was sunk on the 1st of May 1920.

various prison camps in Germany. After recounting earlier steps taken, Sir Gordon Hewart said that on November 25th, 1920, a printed volume containing the complete evidence in the cases in which these persons were concerned was delivered to the German Ambassador for transmission to the Attorney-General at Leipzig. Up to the present the Government had not received information that any one of the selected cases had been brought to trial. Various technical difficulties had been raised by the German authorities, but it was in direct conflict with the facts to state, as had recently been stated, that some of the cases had been settled by agreement or otherwise. It was the intention of the British Government to enforce the trial of these criminals if they were not dealt with by the Leipzig court. Until the end of last year it was impossible to say that there had been unreasonable delay.

England and Wales.

THE EPIDEMIC OF INFECTIOUS FEVER CASES IN THE AUTUMN OF 1920.

A REPORT has been issued by the Infectious Hospitals Committee of the Metropolitan Asylums Board relative to the manner in which the autumn epidemic of infectious fever cases was dealt with. That epidemic was, from the point of view of the numbers concerned, the biggest epidemic with which the Metropolitan Asylums Board has had to deal in its history. During the epidemic of 1919-1920 it was not found possible to receive all the cases of infectious diseases for whose admission application was made, owing to the curtailment of the fever hospital accommodation during the war to meet urgent national needs. Yet only a few months later a task vastly greater in magnitude was actually accomplished with complete success, under conditions from which the war embarrassments had been largely, though not entirely, removed. In the epidemic of 1920, from the beginning of July, when the rise began, to the end of the year, when, although numbers were declining, cases were still being admitted in large numbers, the total number of cases was 23,179, as compared with 19,761 in 1907, which was the previous highest total for the same period. Cases of diphtheria numbered 7,198 in 1920 as compared with 4,145 in 1907. In view of the great difficulty experienced during the previous autumn and winter in securing the nursing staff required, an extensive and systematic advertisement campaign was instituted throughout the country, and some 860 nurses were engaged by the matrons of the different hospitals. Even this number did not satisfy the needs, and it was found necessary to employ nurses from nursing institutes to the number of 197, while at times the staff had to work overtime so that a larger number of patients could be accommodated at the various hospitals. With a view to utilizing the large resources of Joyce Green Hospital, Dartford, in the early stages of the epidemic, arrangements were made in September under which on several days in the week a number of acute scarlet-fever cases were removed from their homes to Rotherhithe, and conveyed to Long Reach by one of the Board's hospital steamers, which on its return brought back recovered patients to Rotherhithe, whence they were taken to the usual ambulance stations for discharge. When, owing to extreme pressure, it was doubtful if the beds could be provided for all cases on immediate application, special efforts were made to admit every diphtheria patient at once; these efforts were entirely successful, except on three occasions, when one or two cases were held over from one evening to the following morning. The vast majority of the scarlet-fever cases throughout the epidemic were likewise removed at once, and no case which the Board was asked to receive was refused admission. It will be realized that the unprecedented demands in connexion with this fever epidemic placed a severe strain on the administration of the hospitals and the ambulance services, and the Metropolitan Asylums Board has very rightly conveyed to the medical superintendents, matrons, and other members of the staffs an appreciation of their services.

DISTRICT NURSING IN LONDON.

The change in the economic conditions of the country brought about by the after-effects of the war has caused special attention to be given to the provision of nurses for a class of patients who do not usually seek the services of district nurses. The difficulties in the way of such patients obtaining private nurses arise from various causes. In some cases lack of accommodation makes it impossible to house a resident nurse, and this is found increasingly to be the case in flats. In other cases the economic problem is the chief one, for many patients of the professional classes are unable now to afford the ordinary fees of a private nurse. The annual report of the Central Council for District Nursing in London for the year 1920 states that efforts to meet these classes of case have so far been sporadic and unorganized. In London certain members of the Nurses' Co-operative Association have undertaken the cases of people living in flats and able to pay full fees, but unable to house a nurse; but it appears that such facilities either do not exist in sufficient number or, if they

exist, are not sufficiently known. Some district nursing associations, especially in the provinces, have endeavoured to meet this need, and most of them agree to allow their nurses to visit patients who can make some small payment, usually in the form of a donation. In London this plan has not been largely followed, though several of the associations are now considering the propriety of doing so. It appears clear that services rendered by district nursing associations should be limited to those who cannot pay the fees necessary to put the scheme on a profit-earning basis. A memorandum on the subject has therefore been issued by the Central Council to the Nurses' Co-operative Association and to the District Nursing Associations. The opportunities and the interests offered by district work are necessarily limited in their appeal to nurses, since with that work must also go considerable hardships, needing devotion and self-denial. The District Nursing Associations, while demanding the highest qualifications for their nurses, are unable to offer very attractive salaries; the minimum salary payable to district nurses by associations in receipt of grants has been increased from £50 to £63 over and above board and lodging; and this matter will probably have to be reconsidered in the near future. Even the full three years' training in a general hospital is not considered sufficient to fit a nurse for work calling for resources so varied as that of a district nurse, carried on, as it is, in conditions so different from those prevailing in a hospital, and often needing considerable knowledge of social work in all its many forms as well as practical skill. The district nurse has a share in all the health work of a district, including infant welfare and tuberculosis. Even with the increased grants made possible during last year, several of the associations are finding it necessary to curtail their work and to withdraw nurses. In view of the fact that every effort is being made to cover the districts unprovided with nurses, it is regrettable that such curtailment should be necessary, and a suitable appeal to the public will shortly be put forward in order that the voluntary associations may be adequately maintained. The annual meeting of the Central Council for District Nursing in London was held at the offices of the Metropolitan Asylums Board on February 28th, when it was decided that the executive committee should inquire as to the adequacy and efficiency of the provision of district nursing in the County of London, with a view to systematizing and improving the arrangements, and the desirability of extending the work beyond the area of the county. A report on the subject will be made to the Central Council.

Scotland.

ROYAL MEDICAL SOCIETY.

THE annual dinner of the Royal Medical Society, the first dinner of the Society since the war, was held in the Hall of the Royal College of Surgeons, Edinburgh, and was attended by a large and distinguished assembly. Dr. J. Davidson, senior president of the Society, was in the chair, and the guest of the evening was Professor Robert Muir, M.D., F.R.C.P., of Glasgow University, an old member of the Society. The toast of "The Imperial Forces" was proposed by the Lord Provost of Edinburgh and replied to by Admiral Sir Herbert Heath and General Sir Francis Davies. The toast of "The Guest" was proposed by the Chairman, and Professor Robert Muir, in reply, thanked the Society for having honoured him. Professor Muir then proposed the health of "The Royal Medical Society," giving reminiscences of his student days as a member of the Society. He sketched the history of the Royal Medical Society from its foundation in 1737, pointing out that even at an early period it came to regard itself as an essential part of the medical school, not of the University, nor of the Royal Colleges of Surgeons or Physicians, but of the Edinburgh Medical School as a whole. It had had considerable influence in making old quarrels disappear and in the development of the feeling that the medical school was a common cause. Dr. J. Lewis Owen replied to the toast. Dr. J. M. Watt proposed the toast of "The University and Royal Colleges," responded to by Principal Sir Alfred Ewing, Sir Robert Philip, Dr. George Mackay, and Dr. Freeland Fergus of Glasgow. Dr. J. F. C.

Haslam proposed the toast of "Sister Professions," to which the Rev. Dr. Wallace Williamson and the Solicitor-General for Scotland replied.

GLASGOW MATERNITY HOSPITAL.

A serious position is facing the Glasgow Royal Maternity Hospital, and at the annual meeting on February 25th the main topic of discussion was the financial embarrassment of the past year. In the course of 1920 the state of indebtedness of the hospital to the bank reached a point which compelled the directors to consider the serious question as to whether the hospital should not be closed. The directors put the position before the Board of Health for Scotland, and a conference was held at which representatives from the hospital, the local authority, and the university attended. It was subsequently decided that the ante-natal wards and dispensaries should be closed on January 31st, 1921. A payment of £5,000 to account of the cost of the treatment of indoor ante-natal cases made by the local authority on January 27th enabled the directors to suspend their resolution to close these ward and dispensaries for the time being, but that relief is only temporary.

Ireland.

CENTRAL MIDWIVES BOARD FOR IRELAND.

THE Central Midwives Board for Ireland held a meeting at the office of the Ministry of Health, 33, St. Stephen's Green, Dublin, on February 24th. There were present Sir E. Coey Bigger (in the chair), Sir A. J. Horne, Sir W. J. Smyly, Dr. Charles G. Lowry, Miss J. H. Kelly, Miss Michie, Professor Corby. The Chairman referred in feeling terms to the death since their last meeting of one of their members, Alderman J. C. McWalter, M.D. He proposed a resolution expressing the sense of the loss which the Board has sustained, and conveying to Mrs. McWalter and family the Board's deep sympathy with them in their sad bereavement. The resolution was unanimously adopted.

The secretary reported that at the examination held in Dublin, Belfast, and Cork simultaneously on February 8th and 9th, 68 candidates presented themselves, of whom 61 passed and were granted certificates. The total number on the Midwives Roll of Ireland is now 2,902. A special meeting of the Board was subsequently held to consider the following charges preferred against one of the midwives on the roll: (1) That, being in attendance at a confinement, she failed to take the necessary steps to secure the attendance of a registered medical practitioner, the case being one which required such attendance. (2) That she failed to hand to the husband or nearest relative the form for sending for medical assistance. (3) That she failed to keep any record of the pulse or to keep a correct record of the temperature of the patient at each visit. The Board, after hearing the evidence in support of the charges, and considering a statement furnished by the accused, decided that her name should be removed from the Midwives Roll.

Correspondence.

THE COLLECTIVE OPINION OF THE PROFESSION.

SIR,—In the SUPPLEMENT, February 19th, page 42, appears a Memorandum advising the profession that, on the direct request of the Minister of Health, dated November 26th, 1920, the British Medical Association is endeavouring to form a committee of medical practitioners which shall be able to state that it voices the collective opinion of our profession centrally.

This Memorandum is admirable, in that it clears away once for all a great amount of mist and doubt often deliberately brought about by enemies of our profession. If the Minister, as Dr. Gordon Ward more than suggests, has stated to any other medical body that, unless it is called into collaboration in this matter by the Association, he will not recognize the resultant committee, such communication should be published at once and be dealt with. It

is not an action of interference and prejudging the issue which those acquainted with the present Minister would credit him with.

This opportunity offered by the Minister to the profession, both for its union and through that union for the benefit of the community at large, is so immense that it is profoundly to be hoped that, through jealousies or otherwise, it will not let it slip away and once more show to the world that it is an impossible crowd of individualists—incapable of give and take, with no imagination—which can well be ignored.

Now the body ultimately formed should be such as will fulfil at least these conditions:

1. The Minister of Health, whoever he may be, must be absolutely satisfied that the body is supported by a great majority of the members of the medical profession in active practice, and that in refusing to recognize any other groupings he is not thereby depriving any of their opportunities for being heard.

2. The body itself, must be satisfied that every active has been given an opportunity on its constitution and mandate, and allowed his (or her) due weight in its formation.

3. Every such registered medical practitioner should have had a similar opportunity of satisfying himself.

4. The enemies of the profession within its ranks (whether a society or individuals) must once for all have been deprived of all evidence in support of a possible contention that the majority of the members of the profession in active practice are not supporting such a body.

5. The proposed body must be able to show irrefutably that after negotiating with the Minister it is able to "deliver the goods."

If these conditions are generally approved then it would seem to follow that recognition has been obtained for the necessity of consulting all the members of the medical profession in practice within the United Kingdom, if the proposed body is to receive from the commencement that cordial recognition and support without which it cannot satisfactorily fulfil its aims and objects. For this purpose, therefore, one would advocate that there should be issued promptly, to every such practitioner, with a copy of the memorandum as it appears in the SUPPLEMENT, a questionnaire containing certain principles suggested by this memorandum. The inquiries would seem to be—

A. Are you at present in active practice in the medical profession?

B. Do you approve generally of the memorandum sent you herewith?

C. Do you consider that the proposed medical body

(1) Should represent the views of the medical profession and the medical profession alone?

(2) Should be an immediately and directly responsible body recognizing the authority of its constituents and no other authority?

(3) Should, in its formation, be confined to those constituents directly and intimately concerned in medical politics and trained in expressing opinions on such matters?

(4) Should not profess to promote the interests of the community rather than those of the medical practitioners engaged in active practice?

D. Do you approve of the proposed body being formed of representatives of

The Royal College of Physicians of London.

The Royal College of Surgeons of England.

The British Medical Association.

The Society of Medical Officers of Health.

The Medical Women's Federation.

The Poor Law Medical Officers' Association.

The Medico-Psychological Association.

The Association of Certifying Factory Surgeons.

E. If not, what other medical bodies intimately concerned in medical politics should be asked to become associated with those mentioned in D above?

F. Do you consider that it would be sufficient if this body (formed as in D above) should recognize other medical bodies concerned in medical politics by consultation and co operation when necessary and desirable?

Looking at these questions, the only comments one would venture to make at this juncture are: (a) That if an affirmative majority reply is received to query C (1), it rules out of court the Federation of Medical and Allied Societies, which is a body with a preponderating number of represented lay persons. (b) That if an affirmative majority reply is received to query C (3), it rules out of court the Royal Society of Medicine and other numerous scientific medical and dental societies which have no acquaintance with medical politics and are attached to the Federation of Medical and Allied Societies. (c) That

those who considered that the list given in query D should be extended have the opportunity offered by propaganda to obtain their wishes by securing replies to query E.

If the profession replied in the affirmative to queries C (1), C (2), C (3), C (4), and added the Medico Political Union and the National Medical Union when replying to query E, one would have great hopes for the future. (That the societies referred to in query D should not co-operate would be a calamity.) Both these additional bodies, like the British Medical Association, have refused to have anything to do with joining the Federation, and sweet reasonableness now on all sides might be expected to result in future useful co operation between them and the Association.

Might it therefore be urged that all medical societies concerned in medical politics, all Local Medical and Panel Committees, and all Branch Councils and Division executive committees, as well as individuals, should at once consider this memorandum, and demand of the Association as a first step that every registered medical practitioner now engaged in active practice be given an opportunity of expressing an opinion on the questions at issue, not delaying until it is found to be too late to make their voices effectively heard. In the meanwhile, would the committee of the Council which has the matter in hand refrain from taking any action which might jeopardize the position?—I am, etc.,

Hove, Feb. 26th.

E. ROWLAND FOTHERGILL.

SOUTH AFRICA AND THE BRITISH MEDICAL ASSOCIATION.

SIR,—On a recent visit to South Africa, just following Dr. Macdonald's most successful tour, I was much impressed by the high spirit of loyalty displayed by the profession there to the British Medical Association, and by the strong desire expressed, even by the Dutch members, that a closer union, if that were possible, should exist between the South African Branches and the Home Association.

The local disruption in the Transvaal is, in the opinion of those most competent to judge, confined to a small area, consists of a few malcontents, is only temporary in character, and will, in all probability, soon fizzle out—the action of the recent Medical Congress to defer a decision for another year giving the movement time to expire gracefully.

The Association in South Africa is very much alive, and, while determined upon obtaining greater powers of self-government, it remains loyal to the parent Association.

The reception given to the Association's representative, Dr. Macdonald, was great, and must have been gratifying alike to him and the Council. If the Association desires to retain the Colonial Branches by their loyalty, then the policy of sending out representatives from time to time must be the future policy of the Association, and thus we shall establish an Empire Medical Association, whose Branches will be found wherever the dear old flag flies.—I am, etc.,

Fordebridge, Feb 23th.

T. DUNCAN GREENLEES.

ENDEMICITY OF INTESTINAL PROTOZOA.

SIR,—May I be allowed a few words with reference to your interesting leading article of February 19th upon the subject of the endemicity of human intestinal protozoa?

We have, broadly speaking, the fact that *Entamoeba histolytica* (restricting ourselves for the moment to this pathogenic form) gives rise in this country only very rarely to amoebic dysentery, whereas in many tropical and subtropical districts this disease is prevalent. In England, as in those countries, a certain proportion of the population is known to be infected with the parasite, occurring in the "carrier" phase. The question is, what is the explanation of the marked difference of behaviour of the parasite in the two cases?

I myself have for some time considered that the chief reason therefore may be found in a different "normal" intestinal flora in this country, for instance, from that common in countries where amoebic dysentery is of frequent occurrence. To give an example of what I mean. There is a well known transient complaint, which was alluded to by our men as "gippy tummy," characterized by sickness and diarrhoea, to which many are liable on

first arriving in Egypt, however careful they may be as regards what is eaten and drunk. Such an attack is probably in consequence of some change in the intestinal bacteria, with resulting disturbance until the alimentary canal has become accustomed to this new factor. And it is well known how careful, in general, one must be to avoid gastro-intestinal disturbance on going to a tropical or subtropical country.

Now we know really very little concerning the extent to which some bacterial infection stands in relation with or helps to induce amoebic dysentery. I have previously emphasized (*Journal of the Royal Army Medical Corps*, vol. xxix, 1917, p. 299) that "for the amoeba to give rise to dysentery there must be some lesion or derangement of the bowel—at least, some non-normal condition—lowering its resistance and giving the amoeba its opportunity." And "precisely the same reasoning applies to the intestinal flagellates." I would suggest, therefore, that the primary factor which either lowers the resistance of the bowel, or enables the amoeba to take advantage of a lowered resistance—the result being an attack of amoebic dysentery—is some bacterial infection. Indeed, this suggestion, that a bacterial infection may produce amoebic dysentery in the case where a man is already infected with the amoeba, has been made by Thomson and Mackie (*Journal of the Royal Army Medical Corps*, vol. xxviii, 1917, p. 409).

I do not consider that the suggestions, either of a non-pathogenic strain of *E. histolytica* in this country or of acquired immunity on the part of the population, will account adequately for the difference above noted. In the first place, amoebic dysentery is now known to occur—if very rarely—in people who have never been out of Britain. And I think the following point is of considerable significance: Not only before the war were a certain number of people doubtless infected with what would be regarded as the pathogenic strain arriving regularly in this country, but during the war vast numbers of troops so infected arrived home. And there can be no doubt, further, that a certain number of people who had never been abroad—especially, for instance, recruits—came into contact with such "carriers" and became themselves infected from the carriers' cysts. Yet how many cases of amoebic dysentery have resulted from infection so acquired, not only during recent years, but through all the years since intercourse with the East became general? Very, very few, certainly. But compare, on the other hand, the difference as soon as our troops went East and came into contact with Indian or Egyptian native sources of infection.

The conclusion is forced upon us, I think, that there is some additional, as yet unknown, factor concerned, operating in countries where amoebic dysentery is prevalent, which is not usually operative in this country and others where amoebic dysentery is of rare occurrence. To some extent this factor may be perhaps climatic. But I think, in the main, it is quite likely to be the predisposing harmful influence exerted on the bowel by some bacterial infection to which dwellers in this country are not normally or to nearly the same extent exposed as are those in districts where amoebic dysentery happens to be endemic. It is perhaps not without significance that amoebic dysentery does occur, apparently to a slight extent, among patients in lunatic asylums, where bacillary dysentery is far from uncommon, and where the general bacterial condition and resistance of the bowel may be, for some reason, not what we in this country are accustomed to regard as normal. Again, it may be suggested that "ulcerative colitis," of bacterial origin, may be the cause of the appearance of symptoms of amoebic dysentery in patients who are "carriers" of this amoeba.—I am, etc.,

The Lister Institute, Feb. 22nd.

H. M. Woodcock.

Sir,—Mr. Clifford Dobell's report on the intestinal protozoa endemic in Britain and your editorial comments on the same (p. 276) have interested me, as I have recently examined for protozoa the faeces of 120 children admitted consecutively to one ward of this hospital. In this series *Lambia intestinalis* was present in seven cases, of whom the youngest was only three months old. Of these children four were admitted for diarrhoea. In one case this symptom had recurred at intervals for six years, and had led to a slight degree of impairment of growth. To what extent this flagellate can be held to be responsible for the

diarrhoea in these children it is at present impossible to say, but it appeared to be the only factor in the production of this symptom in the protracted case mentioned, for careful clinical and pathological observations excluded as far as possible all other causes of diarrhoea.—I am, etc.,

February 22nd.

HERBERT PERKINS,
Pathologist, Paddington Green Children's
Hospital, W.

THE CURE OF HAEMORRHOIDS WITHOUT OPERATION.

Sir,—I am in cordial agreement with the main thesis of Dr. Lyth's article upon this subject in the *Journal* of February 19th, that the operation for haemorrhoids is not always successful, is usually unnecessary, and is rarely justifiable. The late Sir James Goodhart wrote to the same effect in the *Practitioner* of December, 1914, and his article led to a series of others by various rectal and general surgeons, printed in the *Practitioner* of March, 1915. Stimulated by these articles, I tried various treatments for haemorrhoids at St. Mark's Hospital, where I was temporary assistant surgeon at that time, and in the *Lancet* of March 18th, 1916, I published a paper on the treatment of haemorrhoids by injection. Since 1914 I have been practising this method of treatment very extensively, and have every reason to be pleased with the results I have obtained.

Whilst agreeing with Dr. Lyth's opening text, I cannot at all agree with his description of the pathology and course of haemorrhoids. Let me at once correct him in his idea that when an internal pile has prolapsed it has become an external pile, in any other sense than that it is now outside the sphincter ani. Internal piles are attached to the mucous membrane of the rectum above the anal valves, and are always covered by mucous membrane and never by skin; they can always be reduced completely into the bowel, unless strangulated. They are essentially different from external haemorrhoids. External haemorrhoids are of two varieties:

- (1) Thrombosed external haemorrhoids, which are inflamed thrombosed subcutaneous varicose veins, and appear as hemispherical, purplish lumps, covered with ordinary skin, and varying in size from that of a pea to that of a walnut. If left alone or treated "palliatively" they subside in two or three weeks, but meanwhile cause considerable pain and discomfort, and may suppurate and cause an anal fistula. They are best treated at once by snipping off about two-thirds of their bulk with scissors and forceps, and turning out the contained clot with a spoon. This little operation can be done painlessly under local anaesthesia, gives immediate relief, and leaves a wound which is usually soundly healed in a week.
- (2) The other variety of external haemorrhoid is the ordinary "skin-tag," which is a pendulous fold of skin growing from the anal margin. Skin-tags as a rule give rise to no symptom other than slight itching, unless they become inflamed or infected, when they can be removed under a local anaesthetic.

Dr. Lyth boldly states that as long as an internal pile remains inside the anus it does little harm. But it is a daily experience of those who see many rectal cases to meet with patients who have piles which have never prolapsed, but who nevertheless have had such frequently repeated haemorrhage that they have been rendered extremely anaemic. I have twice been summoned to see patients who have had such alarming haemorrhage from piles that have never prolapsed that they have been rendered pulseless and almost at death's door. Other exceedingly common symptoms of piles which have never prolapsed are pruritus, pain, discharge of mucus, dyschezia, etc. Without a good rectal speculum (such as Kelly's proctoscope) a pile inside the anus cannot be diagnosed, except by guesswork, because even the largest internal haemorrhoids, if uncomplicated, cannot be felt even by the finger endowed with the most highly developed *tactus eruditus*. Even comparatively small internal haemorrhoids frequently cause quite severe haemorrhage and other troublesome symptoms.

Dr. Lyth's treatment by the frequent application of calamine powder and the constant application of a pad to the anus may have its uses, but I doubt whether it is likely to control haemorrhage from piles of any size, and it is obviously inapplicable to piles which are not prolapsed. On his own showing, if the piles are prolapsed, it will be some six weeks before spontaneous reduction can be achieved even by the patient's adoption of the recumbent posture after defaecation; and even then the patient is only

"in a fair way to being cured." Meanwhile, and even afterwards, he has to wear a pad, to powder his piles frequently, to ensure that his bowels only act at bedtime, and so on.

By means of injections about 90 per cent. of all cases of internal piles can be treated painlessly without operation, and without lying up a single day. In the very large majority of the cases I have treated—which amount to many hundreds—both bleeding and prolapse have disappeared from the moment of the first injection, and in all cases a permanent disappearance of the piles may be looked for after from three to six injections.

Method.

The piles are injected *in situ* through a Kelly's speculum by means of a suitable syringe. The syringe I recommend is a modification of Dawson's dental syringe, which is long enough to use through the speculum. It is stocked by Messrs. Krohn and Sesemann, Messrs. Allen and Hanbury's, and others. The solution I use consists of 20 per cent. carbolic in equal parts of glycerin and water. About 5 minims of this solution is injected into each pile in such a way that the fluid is lodged near the centre of each pile. In the case of a very large pile a few more drops may be injected into its base. A few seconds after injection the pile swells considerably, and its surface turns white. The needle should be kept in position until these changes have been observed, because otherwise some oozing is likely to occur and the fluid will be washed out with the blood. All the piles may be injected at one sitting. Care must be taken to inject too little rather than too much of the solution, because if too much is used there will be a more violent reaction and considerable pain may result. If the correct amount is used, no reaction is used, there is not usually any pain. The patient must be warned that in the case of piles coming down after injection, he must not delay in washing them with cold water, greasing them with vaseline or any ointment, and gently returning them. If this is not done, and the piles happen to come down after injection, they may continue to swell outside the anus and become strangulated. Apart from this, no treatment other than a laxative is required. The injections are repeated at weekly intervals, until examination with the speculum shows no pile present.

I have recently written to all my private patients whom I treated by injections upwards of three years ago. Of those from whom I received answers to my questions I find that 83.4 per cent. report themselves absolutely free from all rectal symptoms. Of the remaining 16.6 per cent. by no means all have any real trouble, because I have included amongst them such cases as those in which the patients have "occasional itching about the anus," "occasional uneasiness," and so on. Amongst this 16.6 per cent., as well as amongst the 83.4 per cent. absolute successes, were several in which I did not advise injection at all, because I found complications which rendered operation the preferable treatment; however, I injected them at their own earnest request, and even in those who are not still well there was a long interval of complete comfort.

This treatment is so simple that any practitioner who will acquire the few necessary instruments and a certain amount of practice may adopt it. But before doing so he must have a clear idea of the difference between external and internal piles, because the method is quite unsuitable for the former and, if employed therein, might lead to very unpleasant results.

I fancy most patients would prefer this treatment, with its practically instantaneous relief, to the treatment suggested by Dr. Lyth, which takes six weeks of messy and tiresome applications to obtain even partial relief and, I venture to assert, almost certain recurrence sooner or later.

Obviously most patients will prefer it to operation, which involves two weeks at least in a nursing home, much expense, a general anaesthetic, and not negligible pain, and which, in my experience (of patients operated on by others as well as by myself), gives no better results as far as recurrence of symptoms is concerned.—I am, etc.,

London, W.C., Feb 23rd.

ARTHUR S. MORLEY, F.R.C.S.

Sir,—It is the duty of all good physicians in these days to protect their patients from the "tyranny" of the surgeon, and consequently the article by Dr. Lyth (February 13th, p. 265) on "the cure of piles without operation" will be of interest to many of us.

As one of those who are of opinion that surgery should be looked upon in many cases as a last resort only, I cannot agree with Dr. Lyth that that view should be pressed too

far when dealing with that most painful of minor affections—haemorrhoids.

No class of case causing the prolonged suffering which is characteristic of inflamed piles responds so swiftly and with such triumphant success to the ministrations of the surgeon.

Meanwhile one is moved to sorrow, if not to a certain amount of unseemly hilarity, at the thought of Dr. Lyth struggling with a mass of acutely inflamed external piles which obstinately refuse to be returned to what he insists must be their proper home within the sphincter. I fear that such intervention could only result in unmerited suffering for the unfortunate patient and great satisfaction in the camp of the enemy who will be called in to repair the mischief.—I am, etc.,

Nov. Feb 21st.

A. H. COPEMAN, M.D.

RISKS AFTER OPERATIONS ON TONSILS AND ADENOIDS IN OUTDOOR CLINICS.

Sir,—I should like to suggest that the dangers and complications of the tonsil and adenoid operation when performed in the out-patient department are not so serious nor so numerous as the letters of previous correspondents might lead one to suppose.

At all the hospitals in London of necessity hundreds of these operations are performed each year, conferring great benefit on the patients. I am, of course, only able to quote figures from my own department, but no doubt statistics from other hospitals would show equally favourable results.

Through the kindness and energy of the London County Council "Assistant Organizer" at Guy's I am able to give the following statistics from all the London County Council school children operated on during the last three years in the out-patient department:

The total number of operations was 2,639; the following complications occurred:

Haemorrhage necessitating admission for two or three nights	2 cases
Haemorrhage after returning home for which a doctor was called in	1 case
" " " " " " " "	2 cases
" " " " " " " "	1 case
" " " " " " " "	2 cases
" " " " " " " "	1 case

In one case Vincent's angina developed in the tonsil bed, in two cases temporary torticollis followed operation, but it is most improbable that these can be ascribed to the fact of the patient's return home after operation.

Expressed in percentages, Haemorrhage occurred in 0.147 per cent., otorrhoea in 0.147 per cent.

Though I have no actual statistics, I can state that amongst some 8,000 operations performed in the out-patient department during the last ten years no death has occurred, though one case was only saved by cardiac massage; nor has there been any case of acute otitis media that progressed to acute mastoiditis.—I am, etc.,

London, W., Feb 23rd.

W. M. MOLLISON.

THE IMMUNIZING EFFECT OF X RAYS IN CANCER.

Sir,—The correspondence with regard to x rays in the treatment of cancer which has appeared in your columns of late cannot fail to be of interest to the medical profession in general. Dr. Morton is the advocate of penetration and yet more penetration. The harder the ray, the greater the electronic disturbance within the tissues; this, of course, is true, and it is also true that if we seek to destroy a malignant growth by direct attack, x rays must reach it in large quantities. But neither quantity nor quality in themselves guarantee success. The gamma rays of radium may fail even in the case of readily accessible tumours, and thus although a relatively enormous amount of this agent may have been available. Then the average hardness of the x ray beam used in therapy has been doubled and trebled within the past ten years; yet will anyone assert that the prognosis of cancer in bone—even thin superficial bone—has been sensibly improved? The ideal of the *therapia stellaris magna* has never yet been reached in medicine. Ehrlich believed he had attained it, but there is now reason to think that salvarsan acts indirectly by stimulating the tissues, as well as by direct poisoning of the spirochaete. The x ray does not destroy cancer *in vivo*

wholly—probably not even chiefly—by an immediate destructive action upon the cancer cell, but by local and general stimulation of the protective mechanisms of the body. Laboratory investigations as to the effects of varying doses of x rays upon cancer masses *detached from their natural surroundings* cannot therefore be in any way relied on to forecast the results of similar doses applied to the living patient.

Experiments designed to raise or lower the immunity of an animal are, of course, in a different category. It has been shown at the Rockefeller Institute in America, and confirmed by Professor Sidney Russ and others in this country, that a single large dose diminishes resistance to cancerous invasion; whereas a series of carefully graduated small doses raises resistance to such an extent that it is almost impossible to get a cancer graft to "take." Whether the rays from a tube "backing up" a 16-inch gap are more effective as resistance-raising agents than those from a tube "backing up" only 10 inches remains to be proved.

The Erlangen procedure, whatever it does to the primary growth, must lower the general resistance, at any rate for a time, thus actually helping any existing metastasis to spread, and likewise any projection of the tumour which may have escaped irradiation. It also produces some skin reaction. The method must stand or fall by itself; it cannot safely be combined with operation. After such dosage he would be a bold man who would submit the skin and subjacent parts to surgical trauma; while as a post-operative procedure it is difficult to see how it can have any *raison d'être*.

Now the tendency at present, in this country, is to seek to combine x -ray treatment with surgery. That this can be successfully done, both before and after operation, can be testified by many, including myself. But the large single dose must be eschewed. Dr. Morton tells us that small doses stimulate a malignant growth. Perhaps a single small dose does; I have no experience. But it is certain that seven or eight comparatively small doses, from a Coolidge tube having a 10-inch spark gap, if spread over a period of about three weeks, will cause a palpable diminution in a carcinoma of the breast, and not in any way interfere with the surgeon's work. A 3-millimetre filter is used, the anti-cathode skin distance is one foot, and the patient is not shielded except as to the face. The current in the secondary is 1.5 milliamperes and the time fifteen minutes.

The action I do not believe to be primarily a local one. In my opinion the treatment acts much as a course of vaccines—it raises the resistance of the patient to cancerous invasion, and places him in a favourable condition for the operation. As to post-operative treatment, the same idea is carried out. Courses of a dozen to eighteen sittings are given at intervals varying from three months to a year, the object being not to kill off any remaining cancer cells by the direct effect of the rays, but to put the body in a condition to combat their growth. That a series of small doses has this effect in animals was proved in the same set of experiments which showed the harmful effect upon the body resistance of large single doses. It will be noted that this system permits of actually shielding the growth itself from the x rays should this be considered desirable.

The results quoted by Dr. Reginald Morton as having been attained at the Erlangen clinic are not wholly convincing—as yet. The number of cases is small, and the observations extend for an average of about three years only. Taken at their face value, they are decidedly better than those obtainable by surgery alone, more especially as regards uterine cancer. Figures for cases treated by a combination of x rays and surgery, with pre- and post-operative raying, are not yet available to any great extent in this country, but there is no doubt but that they show an improvement on surgery alone.

It may be that, at no very distant date, uterine and breast cancer will be treated by x rays alone; but, even then, it does not follow that the Erlangen technique is the only one by which cures can be accomplished, or that there is no apparatus in Great Britain suitable for the purpose. It must be remembered that, so far, British radiologists have had practically no opportunities of finding out what can be accomplished entirely apart from operation, for the latter has been the rule.

British x -ray workers will, I am sure, hesitate long before adopting the heavy dosage advocated in Germany. They remember the skin disasters which were beginning to

come to light just before the war as a result of big doses, although the skin had not at the time appeared to be injured; and if in the near future they are called upon to treat cancer apart from surgery, they are likely in the first place to try out less drastic procedures. To condemn the Erlangen technique would be foolish; it is a serious attempt to substitute x -ray irradiation for surgical operation in the treatment of cancer of the breast and uterus, and it may be successful; but, in the nature of things, the proof or disproof will occupy many years.

Meanwhile, any attempt to secure the wholesale adoption of the method in this country is to be deprecated. I have already had medical men writing to me to ask if I am sure my doses are big enough—if I am certain that I am not stimulating instead of depressing. Such is the effect of a single letter from a man of Dr. Morton's eminence.

Let us clearly understand that the Erlangen technique has not been designed for use in conjunction with surgery, whereas the attempt to "immunize" the patient by comparatively small doses is based on the results of animal experiments, makes surgical operation more easy, and is without risk of sudden catastrophe. So far it is justified by clinical results, and it is at least worth some years' systematic trial.

The use of x rays as immunizing agents in cancer was fully discussed by me in a paper in the *BRITISH MEDICAL JOURNAL* for June 12th, 1920. The immunity is not specific; it is effective in tubercle, Graves's disease, and other conditions. The conception of x rays as resistance-raising agents, rather than substitutes for local surgery, is likely to help much towards that close combination between surgeons and radiologists which is so greatly to be desired.—I am, etc.,

London, W., Feb. 14th.

F. HERNIMAN-JOHNSON.

CONFERENCE OF STAFFS OF VOLUNTARY HOSPITALS.

SIR,—I observe that the Leicester motion, which I vainly attempted to oppose at the London Conference, and against which I protested strongly in a letter to the *JOURNAL*, immediately afterwards (January 1st, 1921, p. 31), has been rejected by the Conference in Scotland in favour of one considerably more modest even than that which I put forward myself as an alternative. I trust that the Leicester motion may now be dropped altogether. Rarely indeed has a resolution so detrimental to the voluntary system been propounded, even by its worst enemies. Had the Representatives in London first discussed it with their own lay committees, and had the Chairman refrained from giving that very strong lead which he did, I am persuaded that the ill-considered motion of Leicester would have received in London the same reception that it has now deservedly encountered in Scotland.—I am, etc.,

Chichester, Feb. 27th.

G. C. GARFATH.

THE POSITION OF ARMS IN BREECH WITH EXTENDED LEGS.

SIR,—The gain to obstetrics from Dr. Victor Bonney's letter of February 16th, in your issue of February 28th, will be specially recognized: it signifies careful clinical obstetrics; it marks the value of museum evidence which, to some of us, brings its daily lesson.

The paper by Dr. W. S. A. Griffith and the late Dr. Arnold W. W. Lea on breech presentation with extended legs, in the *Obstetrical Society's Transactions*, 1897, brought the best of clinical information.

Since that time I have collected relative museum material. Some of the material, the undisturbed foetus, with extended legs at four and a half months within the intact amnion and chorion, and at seven months within the uterus, both confirm Dr. Victor Bonney's description of the extended arms, only partial however, and confined to the lower hemisphere of the head, amounting to this—that if the vertex presented the foot and the hand would be palpable at the periphery of the head.

Eight years ago, after discussing this fact with Sir Francis Champneys, I was supplied by him with the notes of one of his forceps deliveries, in August, 1832, embodying these anatomical facts, which so often escape published description and, probably nearly as often, clinical observation. At that time it was my wish to

have the opportunity of displaying what is now well, if not widely, understood in teaching schools. Of late years the cost of illustration has been prohibitive.—I am, etc.,

HENRY BRIGGS.

Department of Obstetrics and Gynaecology,
University of Liverpool, March 1st.

SIR,—As the medical man unsuccessfully sued for negligence whose experience Mr. Victor Bonney refers to in his letter (February 26th, p. 320) may I mention the following facts?

The case I had to conduct was one of delayed descent with the os dilated. Under chloroform I introduced my hand, and found a breech with fully extended legs (sacro-posterior breech not engaged). Passing my hand above the knee to flex and coax down the leg, I felt a displaced arm passing upward, and at once thought "if I leave that I shall get extended arm when the legs are born," so I followed the arm and found that hand lying flat on the parietal bone. Then I sought the other arm, and found it also displaced upward, elbow forward, forearm above ear, and hand under occiput; I first replaced both arms, then pulled down both legs, the child being large, turning axially at the same time, and delivered without difficulty, the arms coming out in the natural position as replaced.

I have always doubted the truth of the textbook teaching that extension of arms in a breech case can be caused in any way if the arms are in the natural folded position while *in utero*. I believe that in all cases of extended arms there must be some precedent unusual position of the arms; this belief makes it more, not less, important to verify the position of the arms as soon as the umbilicus appears in a breech case. It may mean we ought to verify their position still earlier in labour.

Having in this case lighted on some evidence in support of my belief, I wrote to seven eminent gynaecologists suggesting faulty position of arms *in utero* as the true and main cause of arm extension, and asking if they had ever had occasion to discover the position of the arms *in utero* in a case which subsequently showed extended arms.

One replied that he had sometimes found arms displaced much as I describe; none of them agreed with my theory, but none of them had a case in which, after examination had shown the arms in normal position, the arms subsequently became extended. I suppose they would say because they never pulled unduly, but I suggest that undue pulling will only be followed by extension of arms if the arms are so abnormally placed that extension would occur without undue pulling, or possibly if the pulling is so vigorous that it sets up a reflex causing the child to displace its arms before they reach the brim.

Mr. Bonney now suggests that in every case of extended legs the arms are abnormally placed. I recently had a case of a very small child born alive with ease and with extended legs unreduced (I was called late), in which the arms were normally placed. This does not affect the wisdom of Mr. Bonney's suggestion that in all cases of extended legs the position of the arms should be ascertained, and, if misplaced, replaced. The question in my mind is whether we ought not to go further, and ascertain arm position in every breech case which we see early enough to make so doing easy. I have never yet seen any trouble follow the introduction of my hand into the uterus, and children are lost from arm extension. I think it is debatable. Can any reader record a case of arm extension in a breech case in which he had previously proved the position of the arms to be normal, or subsequent extension in a case where he had replaced misplaced arms? I admit that negative evidence cannot prove my theory, but I maintain it until positive evidence disproves it. I suppose every experienced practitioner has seen cases of arm extension in which no unwise pulling was indulged in, and it is mainly time that the school theory that such pulling is the real cause of arm extension was given up.—I am, etc.,

Finchley, Feb. 25th.

T. H. GODFREY.

THE DROOPING SHOULDER SIGN OF PHTHISIS.

SIR,—In my book, *Tuberculin in the Diagnosis and Treatment of Tuberculosis*, one reads on p. 72, line 16, these words: "This 'habitus phtisicus' manifests itself in the thin, weakly, needy, long, lanky individual with stooping gait and drooping shoulders, a narrow flat chest, wide oblique intercostal spaces, moving but little (paralytic

chest), and wing-like shoulder blades projecting outwards." Certainly Dr. Rivers has not read my book. Comment is unnecessary.—I am, etc.,

W. CAMAC WILKINSON, M.D. Lond.,
F.R.C.P.

London, Feb. 15th.

SIMPLE GOITRE IN SCHOOL CHILDREN.

SIR,—When examining school children in Hampshire I have been struck by the large number of cases of slight enlargement of the thyroid occurring in both boys and girls below the age of puberty. This condition would appear to be much more common in this country than is generally supposed. The thyroid as a rule is not conspicuous, and is seen only if specially looked for. The children are perfectly healthy and robust, but upon comparing their size and weight with those of other children of a similar age, it will be found that they are almost invariably below the average. The condition consequently is not easy to detect unless a number of children of the same age are being examined at once.

Such children are never brought to a doctor for treatment, as they are not ill. The parents frequently do not realize that the child is small for its age, or if so, it is put down as a family peculiarity. I have had no opportunity of treating such children, but should they come under medical treatment for some other condition, it would be well worth while putting them on a course of thyroid or iodide, as was done in the South of France, in the hope of improving their growth.—I am, etc.,

WILLIAM A. LETHBRIDGE, M.C., M.D., D.P.H.,
Assistant M.O.H. County of Hampshire.

Brookhurst, Feb. 27th.

Obituary.

ERNEST COURTNEY LOMAS, C.B., D.S.O.,

Surgeon Captain R.N.

SURGEON CAPTAIN ERNEST COURTNEY LOMAS, R.N. (ret.), died at Pencarnland, East Lothian, on February 24th. He was born on December 24th, 1864, and educated at Owens College, Manchester; he graduated M.B. and Ch.B. of Victoria University in 1888, and took the M.R.C.S. in that year and the F.R.C.S. in 1907. After filling the posts of house-surgeon to the Manchester Royal Infirmary, of senior house-surgeon to the Royal Albert Edward Infirmary, Wigan, and of resident medical officer of the Barnes Convalescent Hospital, Cheadle, he entered the navy as surgeon in 1891. He was specially promoted to staff surgeon in 1900 for service in the South African war, became fleet surgeon in 1904, surgeon captain on September 11th, 1918, and retired in 1919. He served with the Naval Brigade in the South African war, taking part in the relief of Ladysmith, was mentioned in dispatches, and gained the Queen's medal with two clasps, a special promotion, and the D.S.O. During the recent war he was medical officer in charge of three hospital ships in succession. He contributed a description of the equipment and working of hospital ships to the special series of articles published in the *BRITISH MEDICAL JOURNAL* and afterwards collected in the volume *British Medicine in the War*.

SIR HUMPHRY ROLLESTON writes: Surgeon Captain E. O. Lomas's long and painful illness, by necessitating his retirement, was a severe blow to the Naval Medical Service, not only on account of his surgical and administrative abilities, but also for the loss of a specially attractive and lovable personality. He won the D.S.O. for the relief of Ladysmith in the South African war in 1900, and had a distinguished record in the service, his war work being recognized by the C.B. in 1916. He was senior medical officer of three hospital ships in succession; the *Maine* was wrecked off the coast of Scotland before the war, but he was not on board at the time on account of his wife's illness; the *Rohilla* was wrecked off the East Coast late in 1914, and Lomas suffered considerably from exposure before he would leave; the *Garth Castle* was a model and happy ship under his genial and tactful guidance. He subsequently organized and, in October, 1916, opened the Royal Naval Hospital at Granton, near Edinburgh, where I often saw him. Not only was he a most efficient organizer and, until administrative duties

absorbed his time, a keen and capable surgeon, but a most unselfish worker, never sparing himself, while looking after his subordinates in the most kindly way so that they were devoted to him. He was a gallant gentleman whom his friends, and they are many, will long regret.

DR. GEORGE GAUTRY, who died at his residence in Hull on February 18th, aged 57, was educated at Newcastle-upon-Tyne. He graduated M.B., B.S.Durh. in 1887, M.D. two years later, and became M.A. in 1909. He had practised in Hull for thirty years; he was Sheriff in 1908. He took great interest in the Free Church movement and in social affairs, and was a member of the Hull Division of the British Medical Association. He is survived by his widow and five children.

DR. THOMAS POWER, of Poplar, died at his residence there on February 16th. He was a student of Dr. Steevens's Hospital, Dublin, and took the diploma of L.R.C.P.Lond. in 1871. He settled in Poplar soon afterwards, and early won the respect of those among whom he worked. He was J.P. for the borough of Poplar, Public Vaccinator, and Medical Assessor to the Poplar Borough Council. The funeral took place at St. Patrick's Cemetery in the presence of a large number of mourners.

DR. ROBERT WM. GOLDIE died from valvular heart disease at Newbiggin-by-Sea, on February 23rd, in his 75th year. He was educated at Edinburgh University and Westminster Hospital, took the diplomas of L.R.C.P.Edin. and M.R.C.S.Eng. in 1868, and graduated M.D.Edin. in 1887. For twenty-two years he was medical superintendent of the Poplar and Stepney Sick Asylum.

DR. NUSSERVANJI FAKINJI SURVEYOR died of heart failure at Bombay on January 26th, aged 57. He was educated at Bombay University, where he graduated L.M.S. in 1890 and M.D. in 1892; then coming to England he took the M.R.C.P.Lond. in 1892 and the D.P.H.Camb. in 1893. In 1894 he was appointed physician to the Jamsetji Jijibhai Hospital, and at the time of his death was consulting physician to that hospital, and consulting bacteriologist to the Gokuldar Tejpal Hospital, the two chief Indian hospitals in Bombay. He had gained a considerable reputation as a bacteriologist by his researches on the subjects of plague and of madura foot or fungus foot.

Medical News.

PROFESSOR ROBERT BELLAMY CLIFTON, F.R.S., who died at Oxford in his 85th year on February 22nd, was an honorary member of the British Medical Association. He had held the chair of experimental philosophy at Oxford for fifty years (1865-1915). He was elected an honorary member of the Association on the occasion of the annual meeting at Oxford in 1868.

CLINICAL meetings are held at the Western Ophthalmic Hospital, London, N.W., at 5 p.m., on the fourth Wednesday of each month. Medical practitioners and others interested are invited to attend.

A DISCUSSION upon the eradication of tuberculosis in men and animals will be held in the Robert Barnes Hall of the Royal Society of Medicine on Monday, March 14th, at 5.30 p.m. The discussion will be opened by Sir John McFadyean, who will be followed by Sir Clifford Allbutt, Sir G. Sims Woodhead, Dr. Arthur Latham, Professor Hobday, Dr. A. C. Inman, Dr. Halliday Sutherland, Mr. Cyril Nitch, and others. The chair will be taken by the President of the Society, Sir John Bland-Sutton.

A COURSE for the D.P.H. (Conjoint Board in England) will be held at the Technical College, Bradford. The course in bacteriology will be conducted in the public health laboratories by Dr. William Campbell, lecturer in bacteriology and industrial diseases, and Dr. H. Cecil Robertson, assistant lecturer and demonstrator in serology and immunology. The course in chemistry will be under the direction of Dr. R. D. Abell, the head of the chemistry department.

FOR the last twenty years or so there has been some uncertainty as to the future of St. George's Hospital and its medical school; various proposals for their removal to some other site have from time to time been put forward, but we are now informed that this uncertainty has been set at rest. It has been decided that both hospital and school shall remain on their present site. The uncertainty has no doubt been to some extent detrimental to the school, but the teaching has never suffered, and the examination results for the past year have been most creditable. As the number of students recently has not been large, any candidate at all capable had a number of scholarships and prizes open to him, and was certain of getting a house appointment.

THE Medical Officers of Schools Association has convened a conference on "Punishments in the Schools," to be held on Friday, March 18th, at 4.30 p.m., in the Medical Society's rooms, 11, Chandos Street, W.1.

AT a meeting of the Royal Anthropological Institute, on March 8th, Professor F. G. Parsons, F.R.C.S., will read a paper on the head form of the long barrow race, with reference to the modern inhabitants of London, and on March 22nd Dr. F. G. Crooksbank will read a paper on the significance of Mongolian imbecility. The meetings are held at 8.15 p.m. at the rooms of the institute, 50, Great Russell Street, W.C.1.

AT the January Matriculation Examination of the University of London there were 148 successful candidates in the first division and 864 in the second division.

THE late Mr. Robert Francis Samuels of Liverpool has left £1,500 in trust to the University of Liverpool for the foundation of three Samuels medical scholarships in medicine, surgery, and obstetrics respectively in memory of his two deceased brothers.

AT a meeting of the Central Council of the Combined Universities Conservative and Unionist Association, Mr. W. Barnard Faraday, LL.B., barrister, and graduate of Manchester University, and Dr. Sidney C. Lawrence, medical officer of health for Edmonton, and graduate of Birmingham University, were unanimously adopted as prospective candidates for the Combined English University constituency at the next general election.

THE second International Congress of Pathology has been indefinitely postponed, as it is felt that it is impossible to establish cordial relationships between the pathologists of all nations at present.

AT a meeting of the Committee of the Royal Surgical Aid Society on February 15th, Mr. Samuel Watson, who has just retired from the offices of treasurer and chairman of committee, was presented with an illuminated address recognizing his valuable services during the past fifty-one years.

A COMMITTEE has been organized, under the presidency of Professor Luigi Zoja, to commemorate Carlo Forlanini, who died in 1918, by establishing a foundation for the study of tuberculosis. Subscriptions should be sent to Professor Ambrogio Da Grazi, Clinica Medica, Pavia.

THE annual congress of the Ophthalmological Society of the United Kingdom, with Mr. J. Herbert Fisher as president, will be held on May 5th, 6th, and 7th at the Royal Society of Medicine, Wimpole Street. The following arrangements have been made: On May 5th, in the morning, the President will deliver his opening address, and Mr. Maitland Ramsay will read a paper on "A case of cycloitis associated with swelling of the parotid glands"; and in the afternoon there will be a discussion on "The psychology of vision in health and disease," opened by Professor C. Spearman and Sir F. W. Mott. At 5 p.m. the Bowman Lecture will be given by Mr. E. Treacher Collins on "Changes in the visual organs correlated with the adoption of arboreal life and the assumption of the erect posture"; and in the evening the members will dine together. On May 6th, in the morning, there will be a discussion on "The treatment of manifest concomitant strabismus," opened by Mr. C. Worth and Mr. A. J. Ballantyne. In the afternoon the members will visit St. Thomas's Hospital, where a clinical meeting will be held, at which members are invited to show cases of interest. In the evening a number of papers will be read, including one by Lieut.-Colonel H. Herbert on "Results of the his prolapse operation for glaucoma." On the morning of May 7th there will be a business meeting, and further papers will be read. During the congress the ophthalmic papers will be demonstrated in the Bowman Library. Members desirous of reading papers, showing cases, or taking part in the discussions are requested to communicate as soon as possible with Mr. F. A. Juler, 14, Portland Place, London, W.1.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 423, Strand, W.C.2 on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 423, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Attebury, Westrand, London*, telephone 2530 Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Attebury, Westrand, London*; telephone, 2530 Gerrard.

3. MEDICAL SECRETARY, *Medisera, Westrand, London*; telephone, 2530 Gerrard. The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams: *Docilus Dublin*; telephone, 4137, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4351, Central).

QUERIES AND ANSWERS.

INCOME TAX.

"A MEDICAL WOMAN" asks for information as to the expenses deductible and the allowances to be made in the assessment of the income of herself and husband.

* Depreciation allowances cannot be claimed in connexion with professional earnings, and the original cost of motor-car and boat is a capital charge. Estimating the expenses roughly, the assessment of the income should work out somewhat as follows:

1 Husband, gross earnings	£200		
Wages and running expenses of motor, say	£100—£150	0	0
2 Self, gross earnings	£610		
Wages and running expenses of motor etc	£150		
Rent and other necessary expenses	£100	£250—£350	0 0
		£550	0 0
Deduct 10 per cent. allowance for earned income		£55	0 0
		£495	0 0
Investment income		£27	0 0
Total assessable income		£522	0 0
Personal allowance	£25		
Personal allowance, wife's earnings	£45		
Child allowance	£35—£36	0	0
		£216	0 0
Tax at 5s. in the £		£52	8 0
Less £25 life assurance premiums at 5s.		£4	4 0
		£28	4 0

"A. B." bought a car some years ago for £200; he has now replaced it by a car of the same make but higher horse-power, at a cost of £600, less £200 realized for the old car. The makers have ceased to build cars of the same horse-power as the first one.

* Theoretically the proper deduction to be made for income-tax purposes is the cost of a car of similar horse-power, less £200. The practical difficulty that no such car is now made can doubtless be surmounted by a reasonable estimate based partly on the rise in the cost of the higher powered car or the practice of other manufacturers. We assume, of course, that the original car was not purchased at second hand.

H. G. F. inquires as to the validity of his claims for allowance of (1) depreciation of motor cars, and (2) decoration of consulting room.

* (1) An allowance for depreciation is restricted to the assessment of "trades, manufactures, and concerns in the nature of trades," and by implication does not extend to professions. This distinction will be removed if and when the recommendation of the recent Royal Commission to that effect is carried out; in the meantime all the professional man is entitled to is the allowance of the cost of replacement of the car when that cost is incurred. No reduction of the claim for expenses on the ground that the car is used for non professional purposes would be justified if such use has not increased the total cost of running. (2) The cost of redecoration of the consulting and waiting rooms seems undoubtedly

legitimate expenses, and we have not known any objection raised hitherto. We may add that if our correspondent took over the practice in 1920, his liability for 1920-21 would seem to be determined by the average profits of the practice for the three years ending December 31st, 1919, in which case the question of redecoration would not seem to arise at present.

"T. M. C." asks for additional information in reply to his question (December 18th, 1920, p. 957) as to the effect of his retirement from a firm on December 31st, with reference in particular to payments which the practice may make to him after that date.

* If the past assessments had been made on the basis of the value of the firm's gross bookings less expenses, it would be obvious to all concerned that "T. M. C." would be relieved of one fourth of the assessment for 1920-21 in view of his retirement on December 31st, 1920. Any receipts that reached him in the form of payments for old debts would have been already taxed. The position is, in our opinion, precisely the same where the assessments have been based on cash receipts. When the assessment for 1920-21 was made, it referred to the income of the practice for that year, although it was calculated on an artificial basis, and the tax payable is in respect of that income, and not in respect of the cash receipts on which the tax is in fact calculated. There appears to be no legal reason why "T. M. C." should pay tax on more than three fourths of his share of the firm's assessment for 1920-21.

SHIP'S SURGEON.

"S. S." asks for information on the following points: (a) The present average pay of ship's surgeons; (b) whether it is difficult to get posts as such; (c) to whom does one apply—that is, the marine superintendent or who; (d) is much uniform expenditure necessary for casual voyages; (e) which are considered the best lines to go for? He is a retiring I.M.S. officer, a bachelor of 43, and does not want to sign on for a long period with any one line, but to get about the world on many different lines.

SEA WATER FOR INTERNAL USE.

"HALOID" asks whether there is any preparation of sea salt which can be used to make sea water fit to be taken internally. Two preparations have been suggested to him, namely, bay salt and Tidman's sea salt, and he desires to know whether they have been used internally, and, if so, in what strength.

LETTERS, NOTES, ETC.

AMAZIA (ANASTIA).

DR. A. KATE JARRATT (Bridlington) writes: A girl, aged 13, examined by me, was found to have no left breast or nipple. The origin of the pectoralis major was from the first and second ribs, and when put into action the muscle stood out like a cord in a horizontal position. The mother attributes these abnormalities to a slight blow received by her when three and a half months pregnant. The blow was in an upward direction over the left breast. The condition is, I presume, the one known as "amazia."

INSECT VECTORS OF DISEASE.

DR. H. COMPTON PARSONS (Medical Superintendent, Ministry of Pensions Hospital, Cannon Chase, Hednesford, Staffs) writes: A large queen bee was knocked down by the bacteriologist at this hospital. On examining his quarry he discovered small beads of pus on the front pair of legs containing numerous pneumococci, *M. catarrhalis*, and *B. influenzae*. It is interesting to note that even in February living insects are found carrying micro-organisms for distribution in the food stores.

SIGNS AND SYMPTOMS.

DR. J. LEWIS THOMAS (Newport, Mon.) writes: That precision in language, spoken or written, Dr. Gee of St. Bartholomew's, in his *Essay on the Nature of Asthma*, on page 132, writes "symptoms" or "lesions of functions," and on page 134 defines symptoms as "disordered functions observed in patients during life."

VAGITUS UTERINUS?

DR. M. I. McNIFF (London, S.W.) writes: The following case might be of interest to your readers. I was called to a confinement on January 15th. On arrival I found the patient rather exhausted. She was a primipara aged 40. On examination the os was well dilated, but the head was high up. I administered chloroform and proceeded to apply instruments. When I had them almost in position I heard a baby's cry. I said nothing. Soon there was a second cry, quite plain, and nurse said to me "the baby is crying." The baby cried three times in all, and quite distinct. I hastened delivery as much as I could, but it would be seven minutes or more before I delivered it after the cry. On delivery it was cyanosed, with cord round neck. After a short period of artificial respiration it began to breathe normally, and is now a healthy baby.

SUPERNUMERARY NIPPLES.
DR. JOHN S. CLARKE (Weobley, Herefordshire) writes: In the course of examining between 8,000 and 9,000 men proceeding up to their units at the front I came across one case in which there were a pair of well-developed supernumerary nipples, as described by Dr. F. B. Skerrett (February 12th, p. 254). I also met with one case with a single supernumerary nipple, but in this man's case the supernumerary nipple was on the belly wall just below the costal margin—it was undoubtedly a rudimentary nipple. Both men were Welshmen. I have amongst my patients a woman who has two fully developed breasts, but on the left breast, below and slightly outside the normal nipple, is an accessory nipple. During lactation milk could be expressed and the baby was able to suck from it. The woman refused to allow me to take a photograph, nor would she consent to allow herself to be shown at a medical meeting.

SEVEN GREAT-GRANDPARENTS ALIVE.
DR. S. L. CORRY (Uraidla, South Australia) writes: With reference to Dr. J. Robertson Hall's letter in the *BRITISH MEDICAL JOURNAL* of November 13th, 1920, and "A.G.'s" letter of November 20th, 1920, it may be of interest to relate that in my district is a small boy of 2 years, whose parents, two grandfathers and two grandmothers, four great-grandfathers and three great-grandmothers are all living. Soon after the baby's birth these relatives were photographed as a family group.

PREDISPOSING CAUSES OF CONSUMPTION.
DR. ERNEST KINGSCOTE (London, W.1) writes: In Sir James Mackenzie's letter in your issue of February 12th he states that in twenty-eight years of general practice many of his patients developed consumption, but that most of them were previously ill for many years and under his care for a variety of complaints. It occurred to him that these complaints may have been due to conditions which pre-disposed to consumption. Now, one of these, according to the French school, is gastric dilatation and consequent hypochloridrosis; another is restricted movements of the upper chest. Both of these conditions predispose to consumption. The one lowers the vitality, and therefore the fighting power of the phagocytes, through imperfect digestion, mal-assimilation, and auto-intoxication; the other through imperfect oxidization and retention of carbonic acid gas. These conditions should be recognized early and treated. The fixed lung apices form a convenient nidus for the tubercle bacillus. These fixed apices can readily be made to move again by the breathing exercises for the reproduction of lung elasticity in emphysema and other forms of fixed chest, which I demonstrated before the Medical Society of London on November 8th, 1920. The reproduction of the movement and the consequent dilatation of hitherto unused healthy air vessels also tend to benefit the patient even in advanced cases of phthisis pulmonalis.

"T.B. OFFICER."

DR. E. WEATHERHEAD (Alderley Edge, Cheshire) writes: Is it not time that some one with a respect for the proper use of medical phraseology should call attention to the ridiculous method of abbreviation—"T.B. Officer"—which seems to be rapidly becoming universal, to denote "tuberculosis officer." Whether it originated in the Army Medical Service I know not, but I cannot remember its use prior to the war. This has already taken such firm root that letters are frequently addressed in this fashion, even by Government authorities, and in one report-form at least, issued by the Ministry of Pensions to tuberculosis officers, the place for that officer's signature is subscribed "T.B. Officer for —." Imagine any medical man who specializes in one disease being designated in terms of the micro-organism specific to that disease! The specialist in syphilitic disease would become "S.P. Officer," and so on. Let tuberculosis authorities at any rate discountenance such slovenliness in nomenclature. Is the objection to T.O., that the tuberculosis officer might be mistaken by the uninitiated for the transport officer?

MALIGNANT TERTIAN MALARIA CONTRACTED IN ENGLAND.
DR. W. M. McDONALD, District M.O. and M.O.H. Antigua, British West Indies, writes to suggest that the case described in the note of Professor Glynn and Dr. Matthews in the *JOURNAL* of November 27th, 1920, p. 811, as an example of malignant tertian malaria contracted in the North of England was an example of long-standing infection. His experience of more than twenty years in a highly malarious country is that hundreds of patients with subtertian malaria suffering from headache and feeling tired and out of sorts go to a doctor for a tonic without being aware that their temperature is raised. He mentions the case of a boy, aged 17, whose blood was crowded with crescents; he walked several miles to the surgery for a tonic, received medicine, and went back to his work as a field labourer next day. Such an infection, however, if untreated, will culminate sooner or later in a pernicious attack. Dr. McDonald considers that the blood count in the North of England case, the increase of mononuclears, and the corresponding decrease in polymorphs are indicative of chronic malaria. In his own experience the increase of large mononuclears is hardly perceptible in an initial attack, but grows after each subsequent attack. He has found an

increase of large lymphocytes and a diminution of small lymphocytes a marked characteristic of malarial blood. With regard to the assumption that the patient was infected on September 27th with malarial fever, beginning on September 29th, he writes: During twenty years in the West Indies I have never seen nor have I heard of any new-comer suffering from malarial fever within three days of arrival, although *Anopheles* abound and infection abounds. I should regard it as quite impossible for a patient to show symptoms two or three days after being bitten by infected mosquitos. After reading the history of the case very carefully, I should imagine that this patient contracted malaria many years ago from an infected mosquito in a park or the country round Liverpool. In a place like Liverpool there must be many infected persons from abroad, and the *Anopheles* in this neighbourhood are therefore open to infection. I would suggest that the headaches to which the patient was liable were due to malaria, and that, had her temperature been taken at such times, it would have been found to be slightly raised, and that her paleness and lack of strength were directly due to chronic malaria.

COMBINATION IN THE ELECTRO-MEDICAL INDUSTRY.
AMALGAMATION seems to be the order of the day in the electro-medical and x-ray industry. The Cox-Cavendish Electrical Company, of Harlesden, itself a combination of two older firms, has combined its manufacturing resources with those of X Rays, Limited, of London, comparatively a new but an energetic house. The firms are to retain their separate identity so far as their commercial activities are concerned, but in the designing and manufacture of their apparatus they will share each other's factory facilities, and their research staffs will work together as one organization. It is expected that this combination will result in larger scale production, particularly of high tension apparatus, with consequent economy, not only to the co-operating firms, but to their customers.

AGE AND PENSIONS.

"AETAS" writes: The argument in my letter (February 12th, p. 249) that age is not a cause but a measure of disability, ends up with what appears to be a non sequitur in the statement that "old age is a disability." As the whole subject requires careful thought and reasoning, may I insert a few words left out of my argument by the printer? The passage then reads:

"In practice the disabilities of older soldiers, though very real in economic effect (to compensate for which is the true purpose of disability pensions), are often difficult to define in terms of disease. The truth is, old age itself is, in fact and in effect, a true disability, which requires recognition in disease nomenclature, if only for the convenience of the term in summarizing a state of disability which, being compounded of many ... of disease and strain, does not easily fall: ... existing disease usually is, aggravated by service, and that aggravation cannot pass away."

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 36, 37, 40, 41, and 42 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 38 and 39.

THE following vacant appointments of certifying factory surgeons are announced: Barton-on-Humber (Lincoln), Brading (Isle of Wight), Bromyard (Hereford), Wincanton (Somerset).

DR. O. K. WILLIAMSON, who was recently appointed to the Chair of Medicine at University College, Johannesburg, will not take up his new duties until February, 1922, and will not leave England until towards the end of the present year.

IN sending their new catalogue of French medical books Messrs. Hachette, the well-known French publishers and booksellers of 18, King William Street, W.C.2, state that they welcome inquiries for foreign medical and scientific works.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive post-
stante letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

289. Acute and Tuberculous Meningitis.

MORQUIO, of Montevideo, Uruguay (*Journ. of Nerv. and Ment. Dis.*, January, 1921), discusses the experience gained in over 100 cases of meningitis. The author divides them up from a clinical standpoint into three groups: (1) Acute meningitis; (2) tuberculous meningitis; (3) meningeal reactions. The acute forms include cerebro-spinal meningitis, pneumococcal meningitis, and infections by the streptococcus and staphylococcus, etc. The meningitis of cerebro-spinal origin ran its usual course, and responded to serotherapy. The pneumococcal cases were characterized by sudden onset, well-marked meningeal symptoms, and frequent fatal results. While generally primary, it sometimes followed pneumonia. The tuberculous form occurred in children from 4 months to 15 years of age. The signs differed according to the age of the child. In breast-fed infants the author noted rapid evolution, with convulsions and coma. Older children showed more irritative signs, spasmodic contractions, delirium, etc. Tuberculous infections, again, were mostly primary, but did occur secondary to tuberculous disease of the lung, peritoneum, or joints. The disease not infrequently followed enteric in the author's cases. Tuberculous meningitis in children may be simulated by other conditions. Mumps may produce vague meningeal signs, as may also otitis media, and more rarely congenital syphilis. Rigidity of the neck and Kernig's sign, according to the author, are observed in the early stages of pneumonia, enteric, and severe influenza. The signs may lead to lumbar puncture being performed, when the observer will be surprised to find an increase of tension in the cerebro-spinal fluid. It is clear in appearance, and no chemical or cell changes are found. The author insists on lumbar puncture as a routine in all cases of meningitis. He has found that examination often shows unexpected results. For example, in cerebro-spinal meningitis the fluid may be transparent with lymphocytes from the outset, but, in general, only becomes so when there is improvement. In such a case it is possible to withdraw purulent fluid containing polynuclear cells on one day, and on the next to find the fluid clear and containing lymphocytes. Bacteriological examination is necessary to solve all doubts.

290. Antipneumococcus Serum.

COLE (*Journ. Amer. Med. Assoc.*, January 8th, 1921) urges that in lobar pneumonia the type of pneumococcus concerned should be determined before using an immune serum, which can only be of therapeutic value if it has been prepared by immunizing horses against the particular type of pneumococcus. The serum should be of such potency that 0.2 c.cm. will regularly protect a mouse against 0.1 c.cm. of a culture of such virulence that 0.000001 c.cm. would kill a non-immunized mouse in forty-eight hours. Treatment should be started as early as possible after the type has been determined. The first dose of serum should be from 90 to 100 c.cm. intravenously at body temperature, and repeated every eight hours until the fall of temperature and general amelioration of symptoms. An average case may require from 200 to 300 c.cm., but in a severe late case 1,000 c.cm. may be needed. After use of the serum the blood becomes sterile, local lesions are arrested, and mortality is reduced. The first part of the first intravenous injection should be given very slowly as a desensitizing measure, but if there is much hypersensitiveness it may be necessary to commence with small doses subcutaneously, and the physician should be prepared to inject 0.6 c.cm. (10 minims) of 1 in 1,000 suprarenal extract should severe anaphylactic symptoms occur.

291. Early Treatment in Tuberculosis.

SHIGA (*International Journ. of Public Health*, January-February, 1921) urges protective inoculation for tuberculosis before the appearance of symptoms and in cases in which the diagnosis is uncertain but which may be regarded as possibly infected. Von Pirquet's reaction is a necessary preliminary, not only to show whether or not there is a tuberculous infection, but also to show its intensity, and a marked cutaneous reaction is a favourable indication for vaccine therapy. Before commencing treatment the temperature should be noted for a week in order to determine the size of the first doses, since in febrile

cases caution is needed, whether for treatment or prevention. With actively positive von Pirquet's reaction treatment can be applied at once and will not last long. Injections are given once a week and last about four months. About 300 ambulant cases have been treated with the author's sero-vaccine, 20 of whom received protective inoculation. The results have been most encouraging, the general condition having improved and the weight increased, while such symptoms as slight fever and suspicious breath sounds have entirely disappeared.

292. Congenital Malformation of the Mitral Valve.

OWING to the rarity of congenital malformations of the mitral valve CASTELLI (*Il Morgagni*, December 31st, 1920) publishes the following case. A man, aged 65, was admitted into hospital for cancer of the stomach, and at the necropsy a definite malformation of the mitral valve was discovered. Before describing his case the author briefly refers to 18 more or less similar cases reported by various writers. On examining the heart the left ventricle was thickened, there was slight adhesion between the aortic cusps and there was a small fenestra in the right anterior aortic cusp; the left atrio-ventricular orifice was narrowed. The aortic and lateral cusps of the mitral valve were partly inserted to the upper part of the interventricular septum, which presented an aneurysmal dilatation towards the right ventricle. No other malformations were present in the body. There was some evidence of old tubercle in the right apex. A photographic reproduction of the malformation shows the irregularity of the mitral valve very clearly and emphasizes its difference from most of the other cases recorded. Discussing the genesis of congenital heart disease and this case in particular, the author supposes that the anomalous insertion of the free margins of the mitral valve came about by a process of fusion of the 'chordae tendineae into the muscle of the septum before its closure. Probably on this congenital malformation recurrent inflammatory attacks were superposed at various periods both intra- and extra uterine. Good cardiac compensation was maintained, so that there was no evidence of disturbance of the circulation.

293. Fatal Borax Poisoning.

IN a case cited by POTTER (*Journ. Amer. Med. Assoc.*, February 5th, 1921) the patient took what he thought was a saline cathartic. Within fifteen minutes he was seized accompanied by attacks of vomit from five to ten minutes intervals he would cry out that he was strangling or choking. The lips were slightly cyanotic. At intervals of a few minutes he cried out with pain in the epigastrium, and then immediately after he would grasp his throat and complain of difficulty in swallowing, of choking and strangling. Notwithstanding active hypodermic stimulation (½ grain of strychnine and 2 c.cm. of camphor in oil), he died in one of these paroxysms soon afterward. There was no lead line on the gums or other symptoms present or past to suggest lead colic. Chemical analysis of the contents of the stomach demonstrated the presence of 1½ oz. of borax. At the coroner's inquest it was shown that the deceased's mother-in-law, about 80 years of age, had filled the empty saline bottle with borax without informing the family or changing the label, and that it had been placed on the medicine shelf by another member of the family who thought it was a bottle of saline laxative.

294. Influenza Statistics.

IN a statistical analysis of 648 cases of influenza admitted to his hospital in the first quarter of 1920, BUCHHOLTZ (*Ugeskrift for Læger*, February 3rd, 1921) shows that reinfection ran a milder course than the first infection. Thus, among the patients who recovered, 18 per cent. had previously suffered from influenza, whereas this was the case only in 6 per cent. of the patients who died from influenza. The author admits, however, that these figures are not conclusive proof of immunity conferred by a first attack. In 367 cases the disease was complicated by pneumonia, and all the 162 deaths belonged to this group of cases. Only in 6 per cent. was the influenza uncomplicated. Epistaxis occurred in 23 per cent. of the total, a sore throat in 9 per cent., laryngitis and tracheitis in barely 5 per cent., and otitis media in 2.5 per cent. (23 cases). In 43 per cent. of the cases without pneumonia there were signs of

bronchitis; among these cases there were possibly some with bronchopneumonia, for the diagnosis of pneumonia was made only when the physical signs were definitely positive. In about 30 per cent. of the cases with pneumonia the sputum was haemorrhagic. Measurements of the blood pressure showed that a low blood pressure—that is, 90 mm. or less—was of bad prognostic significance when associated with pneumonia. The subsequent course of the cases of pneumonia which did not terminate fatally was usually uneventful, but in two cases chronic fibrosis and bronchiectasis supervened. The degree of cyanosis was of great prognostic value; 80 per cent. of the patients who died were markedly cyanosed, whereas this was the case only in 24 per cent. of the cases of pneumonia terminating in recovery.

295. Thrombosis of the Splenic Vein.

ACCORDING to BAIS (*Nederl. Tijdschr. v. Geneesk.*, February 5th, 1921), who records a fatal case in an anaemic woman in whom splenic thrombosis was rapidly followed by portal thrombosis and infarction of a large part of the jejunum and ileum, 28 cases of infarction of the spleen were collected in 1918 by Nuzum, who recorded also 4 of his own. In only 7 of these 32 cases, however, was the cause of the infarction thrombosis of the splenic vein. In all the other cases the cause was obstruction of the splenic vein or artery by a malignant growth, embolism of the splenic artery, or torsion of the pedicle of a displaced spleen. Little can be said with regard to the clinical symptoms of infarction of the spleen, but pronounced tenderness and pain in an enlarged spleen occurring in the course of a chronic disease are suggestive. Some cases have been described by Ewald in which fatal haematemesis has occurred. In Bais's case the enlarged veins found *post mortem* in the stomach wall pointed to the likelihood of this event. Nuzum regards the frequent occurrence of fever as of diagnostic significance, but Bais thinks that the fever can in most cases be explained by the primary disease.

296. The Treatment of Cerebro-spinal Syphilis.

SCHRÖDER (*Hospitalstidende*, November 3rd, 1920) points out that at one time the opinion was generally held that the influence of potassium iodide and mercury was almost negligible in syphilis of the cerebro-spinal system, notably tabes and dementia paralytica. During 1919, at his hospital, he systematically treated every case of cerebro-spinal syphilis with potassium iodide, mercury, and neo-salvarsan. Repeated examinations of the cerebro-spinal fluid showed that the amount of globulin and albumin could be reduced to normal even in the case of dementia paralytica. As a rule, but not invariably, changes in the clinical picture coincided with changes in the composition of the cerebro-spinal fluid; this coincidence was least marked in cases of dementia paralytica. The author concludes that vigorous and prolonged specific treatment of syphilis of the nervous system may not only arrest the disease, but even effect some improvement; the results of this treatment in dementia paralytica are very uncertain, but not wholly disappointing.

297. Treatment of Intracranial Haemorrhage in the Newborn.

VAGLIO (*La Pediatria*, January 1st, 1921), who records an illustrative case in an infant aged 3 days, draws attention to the efficacy of lumbar puncture in intracranial haemorrhage in the newborn. In his case the child—who was born in a slightly asphyxial condition—forty-eight hours after birth, without appreciable cause, developed a series of convulsions, which increased in frequency and intensity and involved various muscles of the limbs and trunk. After removal of 10 c.cm. of uniformly blood-stained cerebro-spinal fluid under considerable pressure the convulsions greatly diminished in frequency and intensity. The following morning there were still a few convulsions, but they ceased entirely in the afternoon, and subsequent recovery was uneventful.

298. Treatment of Anaemia by Nucleinate of Manganese.

LEMOINE (*Bull. Soc. de Thé.*, November 10th, 1920) alludes to the work of Hannon and Pétrequin on the therapeutical value of manganese; both of these writers had emphasized its value as a tonic, and Pétrequin had even drawn a clinical distinction between chlorosis due to lack of iron, and that due to lack of manganese. Lemoine has employed nucleinate of manganese in cases of anaemia and debility due to acute infections or neurasthenia, and has observed subsequent regeneration of the red cells and increase of haemoglobin.

SURGERY.

299. Compression Fractures of Vertebrae.

BAKER (*Surg., Gyn., and Obstet.*, October, 1920) describes seven cases of compression fractures of the vertebral bodies with delayed symptoms—the so called "Kummel's disease." The characteristic history is one of injury to the back with more or less local pain and temporary incapacity. There is no injury to the cord, and the absence of positive neurological findings leads the medical attendant to put the possibility of vertebral fracture out of court. Sometimes the patient may be up and about within two weeks, and the true diagnosis may not be made for periods of from three months to two years later. The injury is usually a fall, and the site of the compression fracture most often is in one of the lower thoracic or lumbar vertebrae. Pain is apt to be persistent, and subsequent examination will as a rule reveal a distinct kyphosis, or local angulation of the spine, with musculo-spasm. Careful radiography displays a compressed vertebra. Positive diagnosis can only be arrived at through the x rays, and it is most important that these should be clear and sharp. The radiography of the spine is not yet as certain as the clinician might wish. Often a skiagram taken at the time of the injury has disclosed no spinal abnormality, whilst later plates show an incontestable fracture. It is not quite fair to blame the radiographer in all cases for this, for the bony changes probably develop later. In four of Baker's seven cases the initial roentgenograms were negative for bony lesion, and no early treatment was instituted. The treatment is the same as for ordinary fracture of the spine. Late nervous changes must be very rare and generally due to callus formation.

300. Chronic Intestinal Stasis.

CAUCCI (*La Clin. Chirurg.*, May, 1920), in a long article on this condition, synthesizes recent knowledge on the subject and records three cases operated upon successfully by him. Intestinal stasis is three times as common in women as in men—mostly between the ages of 15 and 45 years, never after 55. The cardinal symptoms are habitual obstinate constipation (with occasional secondary colic diarrhoea), pain, and symptoms of chronic faecal auto-intoxication. Acute intestinal obstruction may occur and "false" appendicitis. Marked cachexia, suggesting possible malignant disease, is common. The anatomical changes causing the stasis may be grouped as deformities of the gut, anomalous situation, and adhesions, and the author describes the different varieties, minutely dividing the intestinal tract into three sections—(1) ileo-caecal ascending colon and hepatic flexure, (2) transverse colon and splenic flexure, and (3) descending colon and sigmoid—and discusses the special abnormalities commonly seen in each section. He compares the slow establishment of intestinal stasis to the similar onset of venous stasis from failure of the myocardium. A change occurs in the relation between the muscular power of the intestine and the resistance opposed to the passage of the faeces. The differential diagnosis is discussed and most of the usual difficulties mentioned. He thinks small incisions for appendix operations are a mistake, as one ought to be prepared to examine more than the appendix only in a laparotomy. In operative treatment five possibilities are discussed: (1) plastic fixation of the bowel (now abandoned), (2) destruction of adhesions, (3) appendicectomy, (4) intestinal anastomosis, (5) colectomy—with a preference for a combination of (3) and (4). A bibliography of nearly 300 references is appended.

301. Surgical Complications of Typhus.

MICHL (*Wien. Klin. Woch.*, December 23rd, 1920) states that parotitis is one of the most frequent complications of typhus, and is usually due to neglect of oral hygiene and toxic damage to the gland. It may occur on one or both sides, usually at a time when a fall of temperature is expected. Of nine of Micht's cases four were bilateral. The second most frequent complication is gangrene, which chiefly attacks the lower extremities. Gangrene of the toes often occurs on both sides. Not infrequently the gangrene extends to the legs, either on both sides or to the left leg especially. Bedsores only rarely occur in cases which have been properly nursed. On the other hand, abscesses of the skin and subcutaneous tissue requiring free incisions are frequent, and are very slow in healing. Bronchitis, which is the rule in typhus, often becomes transformed into pneumonia, which leads to pulmonary abscess or gangrene, usually with fatal termination. The pneumonia is often accompanied by a

serous or purulent pleural effusion which requires extensive rib resection. Suppurative otitis media is another complication, which usually makes its appearance in convalescence, requiring paracentesis or, later, mastoid operation.

302. Adenofibromata of the Breast

ACCORDING to POPOVICI (*Chirurg. Jld.*, November 1st 1920), who records an illustrative case in a woman, aged 28, benign tumours of the breast are rare. Of 100 mammary tumours observed by Billroth, 82 were epitheliomata and the remaining 18 benign tumours. Braquehaye, Courie, Iccoe, and Lenormant describe two varieties of mammary adenofibromata—a diffuse and a circumscribed form. Diffuse adenofibromata form large tumours, which involve the whole breast. Circumscribed adenofibromata are at first round or ovoid, but later become nodular or lobulated. Their site of predilection is the periphery of the breast. Adenofibromata are most frequent between the ages of 20 and 30. The earliest age at which they have been observed is 9 years and the oldest 65. Their evolution is insidious and painless. As the tumour grows the breast tends to become pedunculated, and to fall down over the abdomen, as far as the umbilicus, pubes, or even lower. The tumours may reach considerable size. In Popovici's case the growth was 64 cm. in circumference and 2 kilos 200 grams in weight. Binaud and Braquehaye described a case 65 cm. in circumference and 3 kilos 250 grams in weight. The treatment of these tumours is surgical. When the growth is diffuse, or as large as in Popovici's case, amputation of the breast is required, but when it is small, mobile, and encapsulated without infiltration, partial extirpation only is needed.

303. Anterior Bow-legs

BLANCHARD (*Journ. of Orthopaedic Surg.*, January 1921) urges osteoclasis as against osteotomy in the treatment of bow legs, but it should not be undertaken until, under iactitic treatment, the bones have eburnated and become hard. Prior to operation the patient is put upon a iactitic diet of orange juice, boiled fat bacon, cereals with cream, rich milk, eggs, scraped or pressed beef juice, bread with much butter, phosphorized cod liver oil, vegetables, and no tea or coffee. The frequent occurrence of non union after osteotomy is due to the interruption of bone continuity by the chisel, and the filling up of the open space by extraneous material. In the correction of deformities near joints a fear has been expressed that the osteoclast may slip over the end of the bone and injure the joint, but in twenty years' experience with the Grattan-Scott joint the author has never seen a joint endangered. Slow osteoclasis is dangerous, and not more than eight seconds should be occupied in fracturing a bone in the osteoclast. The effect on the mental condition is a marked end result of such operations, the dejected pre operation look giving place to a self confident poise after cure.

304. Breast Enlargement after Prostatectomy.

KONDOLFOV of Athens (*Zentralbl. f. Chir.*, September, 1920) reports two cases in which prostatectomy was followed by enlargement of the mammary glands. In the first case shortly after operation the right breast became hard and swollen. A year later the swelling had disappeared. In the second case both breasts swelled three and four months respectively after prostatectomy. Kondolfov suggests that the prostate may secrete a substance inhibitory to male mammary development, the removal of the prostate would naturally remove this controlling influence. He goes so far as to hazard the opinion that this breast enlargement favours the view that in doing a prostatectomy we remove functioning prostatic tissue and not a sterile adenoma.

305. Pedunculated Cancer of the Larynx

ACCORDING to BURGER (*Nederl. Tijdschr. v. Geneesl.*, January 29th, 1921), who records a case in a man aged 72, pedunculated cancer of the larynx is very rare, since he has to find only two similar cases, reported by Flecker, on record. The clinical picture was that of a benign tumour, as the growth was round, smooth, pale, and freely movable, and it was only on microscopical examination that it was found to be carcinoma. The malignancy of a tumour, arising as it did in this case from the aryepiglottic fold, is compared with the relative benignity of cancer of the vocal cord, confirms the rule of the old French laryngologist Kuschner, who drew attention to the difference between the relatively malignant cancers of the entrance to the larynx as compared with the relatively benign cancers within the larynx. It is therefore neces-

sary in the case of a movable pedunculated and apparently benign tumour of the entrance to the larynx not to exclude the possibility of cancer, at least in persons of a certain age.

OBSTETRICS AND GYNAECOLOGY.

306. Retrospect of Four Thousand Obstetric Cases.

PORTER MATHEW (*South African Med. Record*, December 24th, 1920) states, in a retrospect of four thousand obstetric cases, that his mortality was 1 per 1,000, and gives practical hints ranging over the whole science of obstetrics. In discussing lacerations of the perineum, he suggests that with a more frequent use of forceps the percentage of cases with lacerations has diminished. The chief point he mentions in the management of occipito-posterior presentations is the early manual rotation of the head. In dealing with cases of breech presentation, he emphasizes the importance of doing external version in the eighth month, if necessary using an anaesthetic. The author's remarks on the management of cases with delay in the first stage are interesting. He divides such cases into four groups: (1) where the pains are infrequent and feeble, (2) where there is premature rupture of membranes, (3) rare cases of continuous contraction of uterus before the membranes have been ruptured—due generally to abnormal presentations, such as transverse. These were all cured by partial anaesthesia and rectification of position. The fourth group consisted of cases with spasm of the cervix at the same time as the upper segment of the uterus contracted. He treated such cases with pituitin hypodermically, and suggests that this drug has a dilator effect of the lower segment under anaesthesia as well as causing contractions. He states very emphatically that he never gives pituitin in labour except under anaesthesia. On the question of retained membranes he inclines to the accepted idea that it is better not to remove them manually.

307. Ectopic Gestation

GRAD (*Imer Journ. of Obstet. and Gyn.*, January, 1921) analyses fifty cases of ectopic gestation, dividing them into four groups: (1) Ectopic gestation with negligible haemorrhage, (2) with moderate haemorrhage, (3) with severe haemorrhage, and (4) with fatal haemorrhage. In the 50 cases presented, 37 were of the first group, 4 of the second, 7 of the third, and 2 were fatal. As regards diagnosis, in the first group only 25 per cent, and in the second group 50 per cent, were diagnosed correctly, but the other more serious cases were diagnosed correctly. Dealing with symptomatology, in the first group pain was the prominent symptom in 26 cases, vaginal bleeding in 11, in the second group pain was a prominent symptom in 3 and bleeding in one in the third group the prominent symptom was collapse, and in the fourth group syncope. Patients in the third group have a theadly pulse but a clear mind, and in the fourth group the mind is dulled and the pulse at best shows only an occasional beat. In 45 cases the right tube was involved twenty two times and the left tube twenty four times, showing that gestation occurs with the same frequency in both tubes. In 2 cases the pregnancy was on the right side and once on the left side. G. should be performed in every case, but in the more serious cases of the third and fourth groups the patients require immediate treatment before transportation to the hospital, and he advises infusing gum glucose or saline and gum solution intravenously at once before removal, until a donor can be obtained for a blood transfusion, in addition to the other methods for counteracting shock. The operation in these cases should have for its aim the control of the bleeding and nothing else, and should be done as rapidly as possible.

308. Radiation Treatment of Carcinoma of Uterus

BECLLFE (*Journ. de rad. et de diet.*, January, 1921) reviews critically the radiation treatment of carcinoma of the uterus, as employed in the gynaecological clinic of Erlangen. The method of dosage is the same as that employed by Villard and König—namely, to measure the ionization currents produced in a small air chamber by the action of the rays. This air chamber can be placed in the vagina. The rays used are very penetrating, and are obtained by a 35 to 40 cm. spark gap with a filter of 0.5 mm. of zinc on 11 mm. of aluminium. The doses have been carefully worked out, and are called cutaneous dose, castration dose (that is, sufficient to destroy the cells in a healthy ovary), sarcoma dose and carcinoma dose (that is,

lethal doses for sarcoma or carcinoma cells). Having worked out these doses, the next problem which presented itself was to estimate the actual dose which penetrates as far as the uterus. First, a wooden box filled with water was used to represent the pelvis, and the dose was measured at various depths. At 10 cm. the dose was 20 per cent. of the superficial dose. Using the same size port of entry, and with the tube at the same distance, observations were carried out on the cadaver, and the dose exactly measured in the body of the uterus and in the cervical canal. A third method of checking the results was to use a black glass tube 2 metres long, one end of which was placed against the cervix and contained a fluorescent screen at an angle of 45 degrees. By these various methods it was found what the actual dose at the cervix was, corresponding to the different ports of entry. Three anterior and three posterior ports of entry were used, and in very fat women an extra-vulval port of entry was employed. This made the total dose at the cervix 110 per cent. of a cutaneous dose—that is to say, sufficient for a carcinoma lethal dose. Before treating a patient a certain amount of preparation must be done, the bowels and bladder completely emptied and the latter kept empty. The exact orientation of the tube is very important, and a tube localizer is used. The current is kept constant at 2.3 milliamperes. The total time taken for one application of the rays is about four hours, and the patient is generally given morphine and scopolamine. There are a certain number of risks involved by this treatment, such as nausea and vomiting for many hours. In addition to such minor troubles there is sometimes great diminution in the white corpuscles, and a second dose should not be given for at least six weeks. Combined treatment of radium and x-rays was tried in a number of cases, but the authors did not give any definite opinion as to their results. In conclusion, Bécère points out that although it is much too early to express a definite opinion on the value of this new x-ray technique as employed in Erlangen, yet the results so far obtained in operable cases promise to be much better than any operative measures. Of 24 cases treated, in 23 the tumour disappeared entirely.

309.

Acquired Vaginal Stricture.

PROUBASTA (*Rev. Españ. de Med. y Cirug.*, October, 1920) records the case of a woman, aged 24, who complained of menorrhagia and metrorrhagia; about 4 cm. from the vulva there was a vaginal stricture admitting the passage of a fine probe only and extending upwards for about 3 cm., as shown by rectal examination. Cure was effected by repeated dilatation by means of bougies, tents, and by repeated stretching. The stricture appeared to date from a severe attack of vaginitis, which had persisted for one year during early infancy.

PATHOLOGY.

310. Histology of the Measles Exanthem.

ABRAMOFF (*C. R. Soc. Biologic*, January 22nd, 1921) finds that on the first day of the disease, though the skin appears perfectly normal to the naked eye, yet microscopic examination reveals there the first changes which make their appearance in the epithelium. Vacuolated nuclei are to be found in the deep layers of the epidermis. On the second day, whilst the skin still appears normal, the numbers of such vacuolated nuclei increase and the numbers of such vacuolated nuclei increase and certain modifications are produced in the protoplasm of the epithelial cells; the latter become vacuolated also. The nucleus is pushed to the periphery, assuming a crescentic form, and a clear vacuole completely occupies the cell. When the eruption appears these changes increase and attain their maximum in two or three days. The deeper parts of the Malpighian layer then contain very swollen altered cells, which stand out from the lower limit of the Malpighian layer and penetrate into the dermis. Gradually they become separated from the dermis, lose their nuclei, and are transformed into colourless masses. These masses form in the dermis strands or irregular collections which may attain considerable dimensions. From the fourth day after the commencement of the eruption they begin to be absorbed. They shrivel up and a round-cell infiltration occurs around them. Finally giant cells are formed which enclose these masses. The process then subsides, but its traces are perceptible for a long time. Even in the third week parts of the epithelial layer may still be atrophied and the Malpighian zone may be almost completely wanting. The changes in the dermis make their appearance later

than those of the epidermis, and consist in perivascular infiltrations clearly visible on the second day of the eruption, as well as the formation of the subepithelial cellular masses already mentioned, which may be looked upon as a sign of the absorption of the degenerated products of the epithelial layer. There is no very evident hyperaemia nor oedema of the dermis. Oedema can only be found in the deeper layers below the subcutaneous cellular tissue, especially around the muscles and the glands.

311. A Meningococcus Epidemic in Barracks.

THOMSEN and WULF (*Hospitaltidende*, January 12th and 19th, 1921) have closely studied certain features of a small epidemic of meningococcus infection in a military school containing 275 men. After two men had fallen ill a search was made for "carriers" by a bacteriological examination of the nasopharynx of every soldier. Positive results were obtained in 31 cases, including the men who fell ill. Of this total, 16 showed Type A, with which 90 per cent. of all the cases of meningococcal sepsis in Denmark during the past two or three years have been identified. In 4 of these 16 cases the infection gave rise to symptoms of disease; in the remaining 12 there was no clinical reaction. Of the 16 cases of Type A, 15 belonged to one barrack, and only one to the adjacent barrack. Thus the early isolation of the infected cases in the first barrack would seem to have been effective in preventing further spread of the disease. In 15 cases the "carriers" harboured meningococci of comparatively benign character, differing in essentials from Type A. The barracks ran north and south; the east side was dark and damp, the west side was comparatively dry and sunny. On the east side there were 139 men, on the west side 136 men. But though the number of men was almost exactly equal on the two sides, there were 22 meningococcus-positive cases on the east side, as compared with only 9 on the west side. Of the "carriers" harbouring non-virulent meningococci, 12 were on the east side, and only 3 on the west. As the authors' diagrams show, the meningococcus-positive cases occurred more or less in groups, two or three adjoining beds being occupied by "carriers," while another series of adjoining beds would prove meningococcus-negative. The authors suggest that the comparatively high incidence of meningococcus infection on the dark and damp side of the barracks should be correlated with the devitalizing effect of these factors on the human organism.

312. Demonstration of *Spirochaeta pallida* in Tissues.

WARTHIN and STARRY (*Journ. Amer. Med. Assoc.*, January 22nd, 1921) present a method which they consider a great improvement on their first method, in that it possesses these advantages: (1) The time is much shortened, the entire procedure may be carried out in less than one hour after the sections have been mounted on cover-glasses; (2) the results are more certain. Spirochaetes have been demonstrated in tissues by this method when all other methods have given negative results. Tissues are fixed in neutral formaldehyde, embedded in paraffin. Sections are cut and mounted on cover-glasses with albumin fixative. The paraffin is removed with xylene, alcohol, water. Next the cover-glass is rinsed with the section in 2 per cent. silver nitrate; the wet section is covered with another perfectly clean cover-glass, so that they are held together by capillary attraction; then they are placed carefully in a bottle of 2 per cent. silver nitrate and placed in an incubator for from thirty minutes to one hour. They are removed from the silver nitrate and the cover-glasses separated. The cover-glass with the section is then placed in this reducing mixture:

Two per cent. silver nitrate solution	...	3 c cm.
Warm glycerin	...	5 "
Warm 10 per cent. aqueous gelatine solution	...	5 "
Warm 1.5 per cent. agar suspension	...	5 "
Five per cent. aqueous hydroquinone solution	...	2 "

After the section is reduced, it is removed and rinsed in 5 per cent. sodium thiosulphate (hyposulphite) solution, rinsed in distilled water and mounted—absolute alcohol, xylene, balsam. The method is described in detail.

The Early Diagnosis of Cholera.

313. PAUSINI (*Rif. Med.*, November 20th, 1920), as the result of experiments on the early bacteriological diagnosis of cholera, concludes that the best results are obtained by strengthening the mixture in peptonized water for six to eighteen hours, followed by culture on D'Arsonval blood agar for twenty-four hours. Microscopic examination of the stained culture is succeeded by the agglutination test; this may or may not be preceded by transplantation on to ordinary agar.

PIONEERS AND EMPIRE BUILDERS: No. 114
FOURTH PERIOD, circa 8000 to 2500 B.C.

Satisfactory Anæsthesia

TRADE
MARK

'WELLCOME' BRAND Chloroform

Reduced facsimile

Satisfactory anæsthesia depends largely upon the purity of the anæsthetic employed.

'WELLCOME' CHLOROFORM excels on account of its exceptional purity and uniformity of action.

It is absolutely free from irritating products of decomposition.

It is characterised by containing precisely that small definite proportion of ethyl chloride which has been found so beneficial in the induction of chloroform anæsthesia.

Issued in hermetically-sealed tins of 30 c.c., and 60 c.c., and in bottles of 2 oz., 1/4 lb., 1/2 lb. and 1 lb.

PORTIONS OF THE HUMAN SKULL OBTAINED BY POSTHUMOUS TREPPANNING AND PERFORATED FOR SUSPENSION AS AMULETS.—Trepanning was practised by Neolithic man, not only for surgical purposes during life, but in order to procure from the skulls of the dead sections of various shapes to which he evidently attached some superstitious or religious ideas. Palæolithic man wore amulets chiefly to aid him in the chase; the Neolithic people—pioneers of so many new ideas and activities—may well have extended their usefulness into the region of prophylaxis. It is interesting to remember that down to the end of the seventeenth century medical properties were ascribed to the substance of the human skull, which was employed in certain maladies of the head. Some of the Neolithic amulets were obtained from skulls trepanned during life, for in them are noticeable the healed edge; the central portion of the lower edge of the broken amulet below shows such traces. These amulets would no doubt be sought as being exceptionally efficacious and sacred. That these objects were not used merely as ornaments, or even as trophies of slain enemies, seems to be proved by the find of one such amulet without a hole for suspension, carefully deposited—through an artificial opening—within the skull of an individual whose relatives or tribe may be supposed to have attached a sacred importance to this rite. These cranial amulets have been polished by prolonged rubbing; some of them have notches and grooves instead of holes for perforation.

CULTURE PHASE: NEOLITHIC

Glaxo is standardised

This fact alone would be sufficient to distinguish Glaxo from ordinary dried milk. Glaxo (Full-Cream) always contains over 25% butter fat and added lactose. The analyses of Glaxo Three-Quarter-Cream (sweetened) and Glaxo Half-Cream (sweetened) are also given below.

STANDARDISED DRIED MILK

Full-Cream :: *Three-Quarter-Cream* :: *Half-Cream*

Remarks

ON

THE INDICATIONS FOR CHOLECYSTECTOMY.

A PAPER READ BEFORE THE MANCHESTER MEDICAL
SOCIETY.

BY

K. W. MONSARRAT, F.R.C.S. EDIN.,

SURGEON TO THE NORTHERN HOSPITAL, LIVERPOOL; LECTURER IN
OPERATIVE SURGERY IN THE UNIVERSITY.

If we may judge by their writings, it cannot be said that the minds of surgeons are yet made up as to whether removal of the gall bladder should be the normal operation in cases of cholecystitis. I quote from two papers, both written by a surgeon of high repute, and both published in the same year. In one, speaking of cholecystostomy, he says "this operation saves this valuable organ for future function." In the other he writes: "Practically all cases of cholecystitis and 80 per cent. of cases of gall-stone disease should be treated by cholecystectomy." In a recent textbook I read: "There is much divergence of opinion on the question of cholecystostomy versus cholecystectomy even among the writers of this volume, some preferring cholecystectomy whenever it can be done, others limiting its use to cases in which the gall bladder is small and shrunken." Examples of the same divergence of opinion might be multiplied.

The question has to be considered from physiological, pathological and clinical standpoints. From the physiological point of view it has to be asked, what is the function and functional value of the gall bladder? It is not found universally among mammals; of the domestic mammals the solipeds, the horse tribe, are without it. The horse has a single ductus choledochus which opens into the duodenum by the way of an ampulla of Vater. The ox, the pig, the dog and the cat possess it. It is present in birds, but in them there are two or more bile ducts, the gall bladder being a diverticulum on that which leads from the right lobe to the duodenum. Physiologists are for the most part silent as to its function, but down to recent years it has been an accepted doctrine that by periodic contractions it floods the duodenum with bile when food passes from the stomach into this part of the intestine. There are difficulties in the way of accepting this theory. It has been pointed out that the amount of bile excreted in the human subject is from thirty to fifty ounces in the twenty-four hours, and that the capacity of the bladder being but one ounce it can hardly be considered a reservoir. This is true for man, who feeds habitually at four or five hour intervals, and whose duodenum contains food at corresponding intervals. Under these conditions the gall bladder can hardly have much functional value as a reservoir determining the admixture of bile with food.

In other animals, continuous feeders, the pylorus is relaxed at frequent intervals to allow the passage of food, and in them there may be a mechanism associating this passage of food into the duodenum with contractions initiated in the gall bladder. The reservoir theory is not to be lightly thrown aside because it does not appear to work in with the habits of man; if it is the true explanation of the function of the gall bladder, then in man this organ is of little value physiologically.

Mr. W. J. Mayo has adopted another theory, that the gall bladder "takes the tension from the common and hepatic ducts, and that the mucus it produces reduces the chances of pancreatic and other complications." This may be called the "safety-valve" theory. It supposes the development of an organ as a safeguard against a possible pathological condition. Such an event cannot be brought into line with any theory of the development of organs of which I am aware. An extraordinarily clumsy way this of avoiding regurgitation of bile into the pancreatic ducts when the other path, the dissociation of biliary and pancreatic ducts, was developmentally open and obtains in many vertebrata.

In the horse, which possesses no gall bladder, subacute pancreatitis has been described only as a consequence of the penetration of foreign bodies; acute pancreatitis has only once been described in the horse, three times in the dog, according to Hutyra and Marck. These figures are of course too small to reason from, but at any rate attention

may be drawn to the fact that these authors are only able to put on record one case in the horse, which has no gall bladder, in which the cause may possibly have been regurgitation of bile into the pancreas, and the horse one of the domestic animals whose morbid conditions have been most thoroughly investigated by veterinary medicine. The "safety-valve" theory practically receives its quashing when we find that in the solipeds the bile duct and pancreatic duct are associated in an ampulla of Vater there is no gall bladder, whereas in the large family which the ox and the pig are examples a gall bladder is present, but the ductus choledochus and the pancreatic ducts open separately into the intestine. There is no real alternative to the reservoir theory, which supposes periodic contractions associated with pyloric relaxation. The dietetic habits of man have, however, rendered reflex of no physiological value to his digestive system.

The gall bladder is a diverticulum with a very narrow neck, the average diameter of the cystic duct being one-eighth of an inch. It is, therefore, a diverticulum in which stagnation may readily occur. In its contents, bile and mucus, most types of micro-organisms can be cultivated, and under conditions of stasis virulence and multiplication are increased. The source of infections in the bile channels is the portal circulation. Under conditions of health bacteria carried to the liver from the alimentary canal and other abdominal sources are destroyed there or so attenuated as to be innocuous. Under pathological conditions this destruction or attenuation is subnormal, and infections of the bile channels may result. Infections of the urinary passages occur under analogous conditions. When infections of the bile channels occur the gall bladder is the site where they tend to persist. One result of the infection may be the formation of gall stones, but the primary condition is that of infection. Whether gall stones form and complicate the infection depends upon the relative proportions of cholesterol and bile salts. Cholesterol is a pure excretion; it is insoluble in water but soluble in solutions of bile salts; when the amount of the latter is insufficient relatively, cholesterol passes out of solution. Cholesterol is thrown off in increased quantity from tissues which are undergoing pathological changes, and concretions formation is a consequence of the rise in the relative amount of cholesterol in bile following infection.

The problem in the treatment of cholecystitis, whether associated with gall stones or not, is to arrest the infection and obviate its recurrence. For anatomical and pathological reasons it appears only remotely possible that gall bladder that has suffered infection and inflammatory reaction can be trusted to remain quiet. We are becoming increasingly acquainted with a group of cases in which without any gross inflammatory reaction in the gall bladder itself, the patient's health is undermined by a chronic cholangitis the nidus of which is the gall bladder, recovered from the chronic cholangitis following cholecystectomy. Some of these patients, if watched over long periods, may show an occasional transient gall-bladder distension and tenderness, but this phenomenon does not always occur. These cases do not come within the scope of this note and I mention them only to illustrate the fact that even the structurally normal gall bladder may harbour an infection sufficient to disorganize liver function and produce chronic ill health. The chances that a bladder and cystic duct structurally damaged by inflammation can be reasonably expected to cease to harbour and engender infection would seem to be small.

The test of a successful operation for cholecystitis is whether the infection of the bile channels clears up, if liver function returns to normal, and the patient does not suffer from symptoms referable to adhesions between neighbouring viscera nor from other symptoms arising from recurrent inflammatory reaction in the operative area. My own experience is that a considerable proportion of cases of cholecystitis treated by drainage fail to pass this test. Admitted that when gall stones are associated with the cholecystitis a return of concretions is unusual when cholecystostomy is performed, a considerable number of patients so treated suffer ill health of one kind or another referable to the persistence of the gall bladder as a centre of infection—ill health due to persistent chronic cholangitis with chronic pancreatitis, recurrent attacks of pain and tenderness in the

neighbourhood of the wound, gastric distension, spasm and sometimes vomiting due to angulation of the pylorus and duodenum by adhesions.

To avoid these complications, to get rid of a potential source of recurrent infection in the biliary channels, it appears advisable to remove a gall bladder which has been attacked by cholecystitis of whatever type. The contraindications are not local but general. In a small proportion of cases it may be advisable, in view of the patient's age or feebleness, to limit the operative procedure to the somewhat less exacting cholecystostomy after removal of calculi if present. With this exception, cholecystectomy should be the rule in acute, subacute and chronic cases. It is necessary to make certain that after its removal no obstruction will remain in hepatic and common ducts. If this is demonstrated beyond doubt, there is no need, even in cases where there is jaundice, to provide external drainage of one or other of these ducts; the indication for external drainage is an associated pancreatitis, and if this is present it is necessary to drain the common duct externally by rubber tube.

Patients who have had the gall bladder removed do not suffer any demonstrable disadvantage from its absence; in the case of cases of chronic cholecystitis they are relieved of the double risk of the re-formation of stones and the persistence

of bile duct infection; in the case of cholecystitis without calculi they are relieved of a diverticulum which would in all probability prove the source of a recrudescence of their intoxication.

An operation field which permits a proper examination of the bile ducts is adequate for cholecystectomy. The operation may present considerable difficulties when the gall bladder is shrunken and lies embedded in adhesions—it is in this condition that its removal is most necessary if recurrent attacks of infection are to be avoided. Under other circumstances its removal is simple. The raw surface left can often be obliterated by suture, or sometimes an omental graft is useful for the purpose. If this is done, and the stump of the cystic duct touched with the cauter, a clean operation field is left in which adhesions are unlikely to form. The operation is altogether a cleaner performance than cholecystostomy in which the gall bladder is opened *in situ*, and some infection of the wound is difficult to avoid. If it is true that the gall bladder is of no particular functional value in the human subject, that it is the nidus of persistent infections in the biliary channels, that its removal is not a more serious operative risk than cholecystostomy, the argument for cholecystectomy as the normal operation in cholecystitis is overwhelming.

ASTHMA AND ANAPHYLAXIS.*

BY
FRANK COKE, F.R.C.S.

THE whole subject of anaphylaxis is of very recent origin; it is also very complex. It will therefore be well to have some general description of this strange phenomenon before passing to the claim that asthma be considered as a symptom of anaphylaxis or protein poisoning, and not otherwise a separate entity.

Charles Richet,¹ in 1902, injected a dog with a dose of poison derived from the tentacles of the actiniae and with no harmful effect whatever. Twenty-two days later he reinjected the dog with exactly the same dose, expecting to reach larger doses later and a condition of prophylaxis to the poison. To his surprise, hardly had he finished the injection when the animal became extremely ill and died in thirty-five minutes. This being the exact opposite of prophylaxis, he called it anaphylaxis.

Numerous experimenters in many countries have since investigated this question; detailed accounts may be found in the books of Richet,¹ Besredka² and Danysz.³

Apart from Richet's experiments, an explanation is found for many curious facts noted previously by Hyman⁴ and others, even by Magendie in 1839. It is found that any form of protein, serum, white of egg, milk, or cereal, has the power of rendering an animal sensitive to another dose of the same protein, which, when given, will instantly produce the anaphylactic syndrome—even to the point of death—in seconds. The next peculiar point is the absolutely specific nature of anaphylaxis. An animal sensitized with horse serum will not react to an injection of beef or any other serum except that from a horse. But no matter what kind of protein is used for the sensitizing and exciting dose, the anaphylaxis resulting is always the same.

The symptoms of anaphylaxis vary in the different animals. The typical picture, applicable even to man, appears as follows:

Provided a sensitizing dose has been given, and a sufficient incubation period of about ten days has elapsed, at the second

or exciting dose the animal is in trouble almost before the injection is finished. It becomes restless, scratches its muzzle as if irritated; the respiration is quickened, then difficult; vomiting takes place, especially in dogs; there is diarrhoea, with the passage of blood; micturition occurs; tetanic spasms and somersaults give place to paralysis and collapse; cessation of breathing brings death. There is marked eosinophilia and other blood changes.

There is at present no complete explanation of this remarkable syndrome. A diagram will serve to visualize the whole subject and to give a rough working explanation of many of the points in connexion with anaphylaxis.

The diamonds, A, B, C, D, represent varying quantities of antigen, horse serum, which are injected into the guinea pig, E to F, below, such antigen being marked by horizontal lines. The body—that is, the blood and cells—is incapable of making use of this raw protein, or of eliminating it as such in the urine, nevertheless it disappears in the blood. Therefore it must undergo some change of a digestive nature inside the blood or cells. (There is no room for exceptions to rules in a short article.) The lower thin line, at F, denotes the potentiality of the blood to produce this internal digestive mechanism and, may be, this is in normal working order to deal with infinitesimal quantities of undigested (by the

bowel) proteins that pass through into the blood and cells from time to time or arrive there through the lungs. Under the stimulus of the protein injected (A), this mechanism (vertical lines) becomes active as it has never been before, and the protein disappears, G to H, until a time comes at the end of some ten days, H, when this digestion is finished and abruptly ceases. An excess of this digestive substance, J, then passes freely into the blood, whilst the further formation of

it sinks to normal, a mere potentiality, as shown by the thin line, K.

There is certainly a moment in the diagram, about H, possibly, too, in the real anaphylaxis it is meant to portray, when there must be antigen and antibody, protein and digestive substance, present together enough to cause a small anaphylaxis. It is at this moment when the serum rashes appear. Is this possibly their explanation?

The blood then contains the antibody or the toxogenin of Richet, the sensibilisin of Besredka, the precipitin of Friedberger, or more simply (here) a digestive substance. The animal is now sensitive. A further injection, B, of antigen horse serum meeting the antibody, J, in the correct proportion, and meeting it suddenly, will immediately cause the anaphylactic syndrome to take place, the large black bar, L. It is now apparent why no anaphylaxis occurs until the incubation period is over. If more antigen is injected during the incubation period, all that will occur is that the time when sensitization

*The substance of a lecture delivered to the Tunbridge Wells Division of the British Medical Association, November 25th, 1920.

appears will be postponed until the increased quantity of horse serum has been digested. But once sensitive, the animal will remain so for years, even for the rest of its life.

Apart from the various theories of the physico chemical or biological upset that takes place in anaphylaxis, it is certain that the central nervous system plays an important part, for under an anaesthetic anaphylaxis will not develop, the animal waking up with the crisis safely passed and with the gain of some measure of immunity or rather desensitization.

No matter what protein is used in the experiments the resulting shock and all its symptoms are always the same.

Passive anaphylaxis. If the blood of the guinea-pig which is sensitive to horse serum, about J, be injected into another guinea pig that fresh guinea pig at once becomes sensitive to horse serum, and a dose of horse serum injected, at once without any incubation period, will immediately cause anaphylaxis. Further than this, if the guinea pig's blood sensitized to horse serum be withdrawn and mixed in a flask with horse serum, the anaphylactic poison, whatever it is, is formed there *in vitro*, and if now injected into a new guinea-pig the latter is seized with anaphylaxis at once.

Anti anaphylaxis of Besredka. A certain sized dose of antigen is needed, and it must be injected quickly to cause anaphylaxis. Anti anaphylaxis is the using up of this excess of digestive substance or antibody J and X by small doses C, when the animal will become desensitized, X, and large doses, D, can then be given with impunity.

It will thus be seen that the horse serum is used in three different ways: as a sensitizing dose A, as a lethal exciting dose B, or as a curative desensitizing dose C. In the desensitization by antigens of human beings who are variously sensitive to these antigens, great care is necessary to make certain that the size of the dose is suitable.

Such is a brief description of anaphylaxis, and it must be clearly understood that the diagram in no way enters into the controversy of how anaphylaxis really takes place; the digestive theory may be wrong from top to bottom, but in the meantime it does give a working explanation of the experimentally observed facts.

The Clinical Side of Anaphylaxis.

True anaphylaxis in man after a second injection of protein is rare, but many cases are on record.

A practitioner in India gave himself a dose of antipneumonic serum, and in a year's time gave himself another. He was instantly seized with fainting fits, coma and asphyxia, and died in a few hours. With the frequency with which serums are now given more of such accidents may be expected. They may be avoided by small preliminary injections, C, the anti-anaphylaxis of Besredka, by giving the injection very slowly, a special syringe—the Woodratt pump—having been devised for this purpose, and by noting any sensitiveness by the skin reactions, as detailed below. If actually developed, anaphylactic shock may be treated by anesthetizing the patient, whilst adrenalin or epinephrin will probably keep minor manifestations in abeyance.

ASTHMA AND ANAPHYLAXIS.

Apart from these very rare cases, there are a large number of complaints which have greater or lesser claims to be considered as anaphylactic symptoms of protein poisoning, and no longer as separate diseases. Chief amongst these is asthma. The case for asthma will be given very fully, and at various points of the argument other complaints that seem to come under the same headings will be noted. Anaphylaxis results from sensitization to foreign proteins. Half the cases of asthma can be proved to be due to sensitization by foreign proteins. In Allbutt's *System of Medicine*, asthma and hay fever are considered together in the same article. Hay fever is due to sensitiveness to pollen, not as a mechanical irritant, but from its protein content. An attack of hay fever can be excited in a susceptible patient by an injection of the pollen protein hypodermically and in mid winter.

Now the sensitiveness to the pollen can be tested for by placing pollen in the conjunctival sac. Test sets for the timothy grass are supplied from St. Mary's Hospital laboratories, where much of the work that led up to the American investigation was performed. Later, this method was transferred to a scratch on the skin, when an urticarial wheal can be produced. Further, it had long been noticed that some cases of asthma were undoubtedly due to the presence of animals—for instance, cats and horses. The next step was to see if a skin reaction could be obtained by the proteins of horse dandruff or cat hair, and the

hundred and one other proteins with which we come in daily contact. To cut a long story short, this method has proved eminently satisfactory and feasible, and by its means the cause of 50 per cent. of asthmatics can be determined,* Dr. Freeman being the first to lecture on this subject in England.

Technique of the Skin Reaction.

The inside of the arm and forearm are cleaned, and a scratch $\frac{1}{2}$ in. long made with a scalpel, not going deep enough to draw blood. On to this the protein and solvent are placed. The tests should be an inch and a half apart. On the two arms a number of tests can be made at a sitting, though sometimes it will take three or even four hours to complete a test. A positive reaction consists of an urticarial wheal not less than $\frac{1}{2}$ in. across. This appears in from ten minutes to half an hour. Sometimes they are as large as a halfpenny with irregular branches coming out of them.

These reactions vary enormously in different people, so much so that some experience is necessary to judge the degree of reaction present. The proteins I use fall into four main groups: Some 70 foods, 20 bacterial proteins, 10 kinds of animal hair, and 10 pollens; also various face powders, etc. A full testing may take four sessions of an hour each.

Very rarely the history is clear enough to enable one to mark the offending protein with the first test, but much time is saved in the long run by a complete examination.

For instance, one patient could only give me a very short time. He was very sensitive to hen feathers. He gave up his feather pillows and feather bed, and his two ciderowns, which he always used for warding off a chill and the asthma at night! Much of his asthma went, but not all. Further testing showed him sensitive to rice and beans, the rice undoubtedly being responsible for his last attack. He is now clear of asthma.

Multiple reactions are very common, as the following case will show.

A child 5 years old, with a strong family history of asthma; eczema and urticaria always; asthma continuously day and night for one year. The skin reactions were banana, cabbage, eggs, and rhubarb + + + +; barley, beans, rye, and oats + + +; beetroot, carrot, chicken, lentil, orange, potato, wheat, and rabbit fur + +; articles to which he was not sensitive were apples, beef, Bird's custard powder, Colman's cornflour, cocoa, codfish, coffee, haddock, herring, milk, lettuce, pear, pork, rasks, rice, lamb, tapioca, veal, horse dandruff, and hen feathers. On a diet chosen from articles to which he did not respond this boy has had no asthma since the first day he came to see me. It surprised me that he should be sensitive to cabbage, but I find that is quite a common thing to be sensitive to. His mother was perfectly certain that fish upset him, I was equally certain that it did not; he now takes large quantities of it. This child had been seen by many eminent medical men in London and Edinburgh both for his asthma and his eczema, but without the skin tests it is difficult to see how a correct dietary could ever have been drawn up.

An explanation is now given to the extraordinary likes and dislikes of these asthmatics in their food, their personal surroundings, and their locality.

A girl, aged 9, had asthma continuously for six years except for a break of eleven months whilst at Exmouth. She came back to London and the asthma recommenced at once, so she went back to Exmouth. There she had asthma this second time, rather worse than she had ever had it anywhere before. This is quite a common kind of history. I was asked to test her in St. George's. She gave horse + + + + +; dog + +; cat + + +. Her "animal history" was that she had always had a cat at home but none at Exmouth the first time. The second time she visited Exmouth there was a cat and a dog there which she played with all the time. She had then been in hospital six weeks with no asthma. She was given the hospital cat to nurse from 5 to 6 p.m. At 1 a.m. she woke up with a typically bad attack of asthma. This explains why so few have asthma in hospital; they leave the article they are sensitive to at home.

One more case. I found a girl very sensitive to dog hair and to nothing else. She got rid of the dog and her asthma went. Some months afterwards she went to the sea and had bad asthma the first night. In the old days she would have stopped there and had asthma for a few days, and then gone home because the "sea air" did not suit her. Having great faith, however, she made inquiries, and found that the people who had left that morning had four dogs, and all four had slept on the rug which covered her bed.

The absolutely specific nature of anaphylaxis is well copied by these asthmatics. Now 50 per cent. of all asthmatics and some 90 per cent. of asthmatic children give reactions. One of the most interesting reactions is that given to human hair, several married patients who are sensitive to it being convinced that they are best when sleeping apart from their husband or wife, as the case may be. It is undoubtedly "foreign"—that is, different from

the blood serum. Hen feathers, chicken meat and eggs, even the white and the yolk, are all different as proteins, and I have had patients sent to me who are only sensitive to one of these.

The following case illustrating passive anaphylaxis, published by Ramirez,⁹ is of great interest:

A man was transfused with 600 c.cm. of blood from a donor, with no immediate discomfort. A fortnight later, on going out for a drive, he was seized with violent asthma, never having had such a thing previously. It was found that the donor he was transfused from was an admitted horse asthmatic, sensitive to 1 in 50,000 horse dandruff protein. His sensitive blood at 7 in the diagram had been transferred to this new man and had sensitized him—to wit, a skin reaction to 1 in 20,000 of the protein.

No less interesting is the fact that another man who received even more blood from this same donor did not develop asthma. What was there in his blood that had avoided sensitization? Or was he sensitized but did not show it by asthma? Their blood groupings are not stated, but presumably they were the same.

Certain individuals are sensitive to other things than proteins.

I examined a patient who gets asthma at once on taking half a grain of aspirin. Another was recently unconscious for ten hours in an asthmatic seizure after being given a kindly night-cap of 5 grains of aspirin. In other people aspirin, quinine, and iodoforn or antipyrin^{11,12} give rise to a profuse urticaria. If the serum of these people be injected into animals, the animals become sensitized to the drug. They become extremely ill when these drugs are then administered to them, whereas the controls give no symptoms. Pagniez¹⁰ states that, serum from asthmatics having been injected into guinea-pigs, asthmatic attacks can be produced in them by injecting them with a solution of the Charcot-Leyden crystals, which the French consider to be made of tyrosin.

These asthmatics show many other idiosyncrasies to food and other proteins quite comparable to the other symptoms of anaphylaxis. It appears that, given the entry of a foreign protein, it is a matter of luck or pre-disposition what symptoms are called forth.

The connexion between asthma, hay fever, and paroxysmal sneezing is well known. Any of them may be due to pollens, animals' hair or the dust of tea or flour. They simulate the nasal irritation of anaphylaxis. Sometimes a simple hoarseness takes the place of both. Vomiting is common.

One child, who is only sensitive to rabbit fur, vomits, as the father says, at the sight of a bowl of rabbit broth. Another patient, who reacts to a solution of 1 in 10,000 of white of egg, is sick even with the glazing on the top of a bun or with a spoonful of soup cleared with white of egg, an inconvenience that overtakes him in a few seconds. Another patient, who has not taken honey for thirty years because it makes him sick instantly, in spite of this interval still gives a +++ reaction to honey. Those patients who are sensitive to animal hairs must avoid circuses and the Zoo. I had a patient who had to be actually carried out of the monkey house. Another who went to a performance of the "Garden of Allah" only saw the first act.

Eczemas and urticarias are very common with asthma, but even alone they give much the same proportion of skin reactions¹³ and are, in fact, merely symptoms from the same protein cause. The ragweed pollen may cause eczema without any asthma or hay fever.¹⁴ A patient who gives a reaction to one member of a group will very often be sensitive to other members of the same group—that is, the hairs, cereals or legumens—probably because they contain some of the same proteins as those in the article tested. Epilepsy is common with asthma and migraines, and is also in the same category.

While the Americans have devoted their energies to the skin tests, the French go to prove all these complaints as anaphylactic by various blood changes.

Widal, Abrami,¹⁵ and their collaborators have discovered a "crise hémoclasique," as they term it, which takes place in anaphylactic shock, in protein shock, and also in asthma, urticaria, migraine, and epilepsy, in paroxysmal haemoglobinuria, in malaria and other parasitic complaints when large quantities of protein are thrown suddenly into the blood stream, and also in those absorbing proteins from their own wounds; as a side issue on this, the rapid removal of tourniquets, massage, and squeezing of the limb with bandages is contraindicated even in civilian practice.

The "hémoclasique crise initiale" consists of a fall in blood pressure, a leucopenia, the leucocyte count falling

from 12,000 to 4,000 or even less, and many other less easily observed changes in the coagulability of the blood, its refractive index, the colour and substance of its clot.

The "marchand de mouton"¹⁶ had dealt in sheep for nearly forty years, during the last three of which he had become so sensitive to the smell of sheep that he had to give up his trade. In hospital he, of course, had no asthma. For the experiment he entered a pen of sheep. His leucocyte count and blood pressure were taken every few minutes. After two hours both fell, the leucocyte from 12,000 to 6,000. They then rapidly returned to the normal. During this time he felt no difference in himself. At the end of three and a half hours, when the crisis was completely over, he developed a very bad attack of asthma.

Another man had migraine, especially after chocolate,¹⁷ but only at times. He had chocolate each morning in large quantities, followed each time by a normal digestive leucocytosis, until there came a morning when the blood pressure and leucocyte count both dropped. Shortly after this gastric disturbances and a bad attack of migraine came on.

In all cases the blood crisis passes without any knowledge of inconvenience to the patient, but, having passed, the asthma or migraine at once develops. With certain cases of paroxysmal haemoglobinuria all that is necessary to initiate the paroxysm is to place the patient's hands in a bowl of very cold water. The blood crisis follows at once, and later the haemoglobin appears in the urine.¹⁸ But because these blood changes are present in this variety of conditions and after the injections of proteins into the blood, it does not, of course, necessarily mean that they must all be true anaphylaxis. Besredka² says that naturally intravenous injection of large quantities of foreign protein, or what not, will give rise to a shock, but he refuses to call these various intravenous protein shocks anaphylactic, unless the same shock is caused when the substance is injected intrathecally.

Cowie and Colloun,¹⁹ in their article on the blood changes in connexion with the non-specific protein therapy by means of injections of antityphoid vaccine, note this same initial leucopenia, etc., of the "crise hémoclasique" but differentiate this protein shock from that of anaphylaxis by the absence of an eosinophilia. This increase of the coarsely granular cells staining with eosin is always present in anaphylaxis. Of other complaints in which it is noted in man, the asthmatic attack is the one of all others in which it is most extensively found. The sputum may be packed with them, in the blood they may be half the number of white cells present. Eosinophilia may, then, be another link to bind these anaphylactoid conditions together. Moschcowitz²⁰ notes that it is present in the subjects of asthma and hay fever, and in their secretions, in the urticarial wheals and bullae of a great many skin diseases, in mucous colitis, in pellagra, and after an injection of tuberculin, in tetany, hemiparesis and epilepsy. It is also a point of great diagnostic value in intestinal parasites. Note the common occurrence of epilepsy, urticaria, even asthma, with worms—that is, an absorption of foreign protein?

Now what of the 50 per cent. of cases in which we do not get a reaction? One is surprised to find how little interest is taken in those cases by the Americans. The type of asthma, excluding the cardiac or renal air hunger, is exactly the same as those in which we get reactions. Probably the fault lies in our not having a sufficient list of proteins to try them with. There are many different proteins in a grain of wheat. I have six in my tests. Also think of the number of protein derivatives there are in the digestion of foods, the scores of microbes inhabiting the bowel, the hundreds of non-pathogenic organisms, many unnamed and unknown to us, but each with its specific protein to which we may be sensitive. There is also the question of a period of desensitization after attacks to be considered.

Chronic Anaphylaxis.

Danzs, the French bacteriologist, has recently published a book which is creating considerable excitement amongst the few who have read his work on *Maladies Chroniques*.

He attributes to sensitization to intestinal microbes or other proteins, not only the attacks and exacerbations of chronic complaints from frequent anaphylactic upheavals, but states that the actual presence of antibody or our "digestive substance" in excess is the cause of most chronic complaints. Fresh antigen may then precipitate big attacks of asthma, urticaria, and so forth, or may by smaller doses cause such complaints as psoriasis, eczema, neurasthenic and menstrual disorders or stomachic upsets.

It is necessary always to bear in mind the double poisoning of microbes and other substances, one in virtue of their toxins, the other in anaphylactic response to their protein content.

The following experimental work backs up Danysz's claim:

Rabbits are given doses of horse serum daily for two or three months with no ill effect. In this way a maximum quantity of the digestive substance is formed. Now if the animals be left for three months without any injections it is found that some will have paralysis, others skin troubles with alopecia, others arthritis, in fact at the end of a year they will nearly all be dead. They waste and in every way copy the chronic complaints that man is heir to.

How do Asthmatics become Sensitive?

In many there is a strong family history, not to the actual protein but to asthma and like diseases. A horse asthmatic father may have one child with hay fever, another with asthma and sensitive to potatoes and hen feathers. There is often a history of fever or inflammation of mucous membranes which has allowed the sensitizing protein to pass through.

Schloss's boy¹² had albumen water for diarrhoea when only a few days old, when egg albumen can pass through the intestinal mucous membrane; this was his sensitizing dose. He next had his first spoonful of egg, the exciting dose, at fourteen months, and it nearly killed him.

The long-continued presence of a protein may make people sensitive to it. I have a patient who has been a baker for twenty years; he is now an asthmatic, very sensitive to wheat and oats.

We will now go over a case of asthma in the light of this new work.

More important than the age is the age of onset. The younger the patient the more simple the cause, the freer from bronchitis and bacterial infections or sensitizations. Ninety per cent. of children give reactions. But no matter what age the patient may be, the chance of finding the cause by the skin reactions increases in proportion to his youthfulness at his first attack. Patients 60 years of age will give reactions if they started their asthma in childhood; whereas in those commencing after 40 very few give reactions except clear cases of occupational sensitization, as the butcher and the baker. The chief points in the history are to know if the complaint is continuous or arises only at certain times of the year or in certain places. If the asthma is constant, have there ever been times when the patient has been free—on a sea voyage, for instance?

The family history merely denotes the predisposition and will not help us to the protein at fault. The pre-natal history will not help either, but is intensely interesting. Like everything else in asthma, it is completely paradoxical.

One patient's mother had seven children. Her husband was a horse asthmatic. With one child, a boy, she had eczema all the time she was pregnant; that boy is a horse and dog asthmatic, all the rest of the children being normal. Another lady has had asthma ever since she was married, very badly and always, excepting for nine months when she was pregnant. The child, a boy, is healthy. I have had a similar history with a migraine patient. Another lady had only had hay fever twice in her life, on both occasions during the whole summer that she was pregnant. One of her sons is a horse asthmatic, the other has had hay fever. Another patient, sensitive to milk, had to have chloroform and morphine every day and night during her two pregnancies. She did not nurse either child. One child was very ill for the first six weeks with gastric troubles after milk; the other, on milk also, died from asthma at 6 weeks of age. This was probably true transmission of sensitiveness to the offspring, as can be produced experimentally in animals. It soon passes off, as it did in the first child.

A history must be made of any distastes for special foods, of the animals present in the house, of microbial diseases, or of the effect, as known, of pollens. Next to the skin reactions, histories of treatment are interesting when seen in bulk. Every article that can be a cause of the asthma must be tested for. Too much reliance must not be placed on the history. One child was very ill in the country during the haymaking season, but better at the seaside. He was not sensitive to pollens, but to oats, etc. He had much oatmeal in the country, and none at the seaside. A complete physical examination must be made; one must not miss tuberculosis even if the reactions give the cause of the asthma.

There is often a history of colds that are said to cause the asthma. More often than not the sneezing and the catarrh is true asthma; certainly, in children, the asthma is often preceded by a year or more of colds and bronchitis. Exercise and dust will often bring on an attack, but they are not the cause. If one finds the cause, the mother will write to say: "It is so nice to see little Tommy running about with the other children and not getting asthma." If the cause can be discovered and it is one that can be removed, the patient will lose the asthma from that moment. Conversely, if the asthma does not go, the cause or all the causes have not been discovered.

There is not space to discuss, nor do we know, the actual mechanism whereby these various proteins act, but there would seem to be two types of patients—those whose mucous membranes respond as quickly as do skin reactions, a matter of minutes, and others whose attack comes some hours after meeting the protein to which they are sensitive, as in my cat case and in the "marchand de mouton." Lastly we must not forget the remarkable part played by the nose in asthma. Occasionally the nasal surgeon will cure patients for varying lengths of time by simply cauterizing the nasal mucous membrane.

Whether the smell of animals actually contains protein which enters with the breath, or whether some central nervous mechanism is set in motion directly through the olfactory nerve is still a matter for investigation. Very little work has been done in connexion with the sense of smell, but the mechanism is extraordinarily sensitive. Now, normal people in the presence of a horse must breathe in just as much of the smell or protein of the horse as these asthmatics. Is it simply that their blood is not sensitive to the horse protein? Or is the protein stopped at the mucous membrane of normal persons? Or does it get through, but is summarily dealt with in normal persons? Again, can this possibly have any bearing on the faces that stamps the ostler and the groom so unmistakably?

Starting with one drop of a 1 in 100,000 solution, I have produced a bad attack of asthma by reaching an overdose at 5 minims of a 1 in 10,000 solution. If the patient is sensitive to articles which cannot be avoided, that is, chiefly horse-hair or pollen, he can be desensitized to either by gradually increasing but very small doses, always controlled by skin reactions. Another treatment is that by the intravenous administration of peptone,¹³ on the idea that all these proteins are broken up into peptones during digestion, and therefore the one peptone may, so to speak, catch them all at a lower level than the specific proteins. The third method is also a method of anti-anaphylaxis, but instead of using small doses of peptone, as antigen, mixtures of microbes from the ordinary intestinal flora are used hypodermically. This is the method of Danysz. He uses autogenous and heterogenous cultures of all the intestinal microbes that will grow on a sloped gelatine or peptone culture. They are used as antigens, not for any toxins they contain, but simply for their protein contents.

By these various methods most cases can be improved, some made gloriously well. The delicate child cooped up in a stuffy nursery each winter with the cat, the dog, or the feather bed that is causing all the trouble, becomes normal straight away. It is impossible to tell which case will give reactions, or which will improve under any particular method of treatment. The method of Danysz must be used with very careful dosage or big attacks of asthma may come on, the patient even being made worse for a time.

With regard to the treatment of disorders allied to asthma, still scantier claims must be made because of the small number of cases coming under any particular heading. The following case is of interest:

A gentleman, at one time a fine athlete, has suffered from neurasthenia and gastric disturbances since the war, feeling blown out after his meals, and in a condition that might well be called hypochondriacal. On testing he is found to be very sensitive to potatoes. Removing these from his diet has made him a different man.

The treatment of Danysz in some cases does give the extraordinary results claimed for it, especially in chronic eczema and other skin diseases. I am, however, convinced that we have yet much to learn in the dosage of these entero-antigens.

If we look back at our diagram and see that the size of the dose alone decides whether it shall be a sensitizing dose,

an exciting dose, or a curative dose, we may well be puzzled in finding the correct dose in a sensitive patient.

Summary.

1. By the skin reactions half the cases of asthma can be proved to be due to some foreign protein.
2. If these causes can then be removed the patients are relieved of their asthma at once.
3. Much can be done to relieve or even cure other cases which do not give positive skin reactions, by the usage of various proteins, as antigens, to desensitize them with.
4. Asthma, hay fever, urticaria, eczema, migraines, epilepsy, and paroxysmal haemoglobinuria, have many common traits and will probably all be proved eventually to be symptoms of anaphylaxis and not separate diseases at all. This list will most likely be considerably enlarged.

In conclusion I wish to thank those many gentlemen whose patients I have tested and treated, but especially my friend Dr. Latham, through whose interest my attention and work have been so fully turned to this matter.

This new advance in medicine may be only a matter of inches, but it does allow us to see round a fresh corner and to obtain a view, and a direct view, of great possibilities in connexion with these chronic complaints, the cause and cure of which have so long baffled explanation.

CHRONIC RETENTION OF URINE ARISING FROM PROSTATIC DISORDER:

ITS CAUSE, AND TREATMENT BY THE PRACTITIONER WITHOUT OPERATION.

BY

HERBERT T. HERRING, M.B., B.S.,

LONDON.

Chronic retention of urine is most commonly produced by some disorder of the prostate gland, and among these troubles enlargement is that most frequently met with. Retention therefrom was generally attributed to a pure mechanical cause, that is, the urethra was blocked or plugged by the intervention of a mass of abnormal gland tissue, which was thrust into the orifice during micturition, thus preventing the escape of urine. Many mechanical theories, based on this principle, have been advanced. At one time it was a large middle lobe which dropped into the orifice like a ball valve. At another it was side-flaps springing from the neck, which met together in the middle line like flood-gates. At a third it was the regular enlargement of the glands round the orifice which prolonged the urethra as a solid projection into the vesical cavity and prevented the escape of fluid, much as an excise-man's inkstand does when upset. And finally, the post-prostatic bar was accused of causing the mischief, for it was said that the bar came forward over the outlet during vesical contraction and effectually blocked it, while at the same time the pressure produced a deep pocket or pouch behind the prostate. None of these explanations appear to be entirely satisfactory. For their supposed action is not supported by the facts disclosed during the use of a catheter; neither do they account for many of the symptoms frequently met with; and finally, the removal of the irregularities—valves, flaps, nipples, bars, etc.—does not invariably restore the lost function. The whole prostatic tissue must be enucleated to ensure success. It would seem, therefore, that although mechanical obstruction may assist, it is not the principal cause of retention.

Before giving yet another explanation, on a different line, a brief sketch of the various pressures existing in the bladder and urethra is necessary to make the argument clear.

Urine within the bladder, when the organ is quiescent, is always subjected to pressure—namely, that due to the force exerted by muscle tone, and to that of the weight of the viscera above. For convenience these two forces are considered as one, and may be termed "tonal bladder pressure." It is found that this tonal pressure increases as the bladder fills—thus, for instance, when empty the pressure may register 15 mm. of mercury, but when holding 10 ounces of urine it may have risen to 30 mm.

The escape of urine is prevented by the resistance the prostatic urethra offers to dilatation. The channel is always tightly closed, and is only open when the pressure on the urine in the bladder exceeds its power of resistance. It therefore follows that as urine does not escape until the act of micturition—that is to say, not until a muscular contraction is evoked—this prostatic resistance must always be greater than the maximum tonal pressure, and if the latter is known by experiment, then the pressure of prostatic resistance must be in excess of that figure. The resistance throughout the length of the prostatic urethra is not equally distributed: it is least at the commencement and increases gradually towards the apex of the gland, where it is the greatest. The total resistance of the whole passage may be said very roughly to be between 40 and 50 mm. of Hg, and it is possible that its maximum is attained with an empty bladder, decreasing slightly as the organ is distended.

When the rise of the tonal pressure, due to the gradual filling of the bladder, approaches that exercised by the prostatic resistance, urine begins to make its way into the first part of the prostatic urethra, which then becomes an integral part of the bladder. As the invasion advances the reflex centre controlling the muscular power of the bladder is stimulated, and the desire to micturate is induced. Should the call be inconvenient, extra resistance is immediately imposed on the urethra by the contraction of the various bands of voluntary muscle distributed around the passage and also by the compressor urethrae muscle. The augmented opposition to the pressure in the bladder, and possibly the expulsion of the urine which has invaded the passage, checks the escape, and the slight wave of contraction which has swept over the bladder wall slowly dies away and with it the desire to micturate. If, on the other hand, the call is complied with, the muscular bladder wall is thrown into contraction, the prostatic resistance is overcome and the urine issues in a steady stream. During the act the voluntary muscles, if desired, may be called into play, so that more resistance is interposed; the stream then lessens, and finally stops, and urine is voluntarily left behind in the bladder. The muscular expulsive power of the bladder is found to behave similarly to that of the tonal pressure, for it is strongest when the bladder is full, and falls as it empties, but it differs in that it ceases directly evacuation is complete. The expulsive force, for instance, with 10 oz. of urine in the bladder may record 180 mm. of Hg pressure, but with 5 oz. it has fallen to 50 mm. or less, and with an empty organ there is none, only that of the tonal pressure of 15 mm. being registered. Further, under normal conditions the whole power the vesical muscle is capable of developing is not invariably called forth, the amount generated being tempered to the work that has to be accomplished, and normally there is always a good margin of reserve power.

The act of micturition is therefore effected, first, by the steady rise of the tonal pressure as the bladder fills, which gradually forces urine into a portion of the prostatic urethra, there stimulating the area governing the bladder muscles; secondly, by the contraction of this bladder muscle, which develops sufficient power to overcome the prostatic resistance.

Normally the two forces—bladder expulsive power and prostatic resistance—are so balanced that they allow of the complete evacuation of the bladder and nothing more. If, however, the balance is disturbed, as is frequently the case in disease, disorder of the act of micturition must follow. Thus, if the prostatic resistance is increased, the expulsive power remaining the same, then a point will be reached during evacuation and before the bladder is empty

at which no more urine can be thrown out, and residual urine is the result.

Again, it is obvious that if the resistance exceeds or is equal to the maximum expulsive power the bladder is capable of exerting, total retention will follow and no urine can be passed naturally. On the other hand, if the resistance is diminished below the normal, then the bladder capacity will be smaller, and the patient will pass urine more frequently but in smaller quantities.

That prostatic resistance is generally augmented by enlargement is amply proved, not only by clinical investigation of the canal and by the fact that removal of the whole tissue restores the lost power, but also by the anatomical and pathological features the gland presents. The prostate is surrounded laterally and below by a very strong fascial capsule. This space is filled with simple and compound racemose glands lying in a groundwork composed of elastic, fibrous, and muscular tissue. Any glandular growth will tend therefore to advance along the line of least resistance—namely, towards the lumen of the bladder, but at the same time will press upon the urethra, which pierces the mass centrally, and will consequently offer increased resistance to any dilatation.

For the foregoing reasons it is contended that retention from prostatic disorder is mainly caused by increased prostatic resistance, and not so much by mechanical blocking as was formerly suggested.

Treatment of Retention caused by Increased Prostatic Resistance.

The tendency at present is to operate on all cases in which retention has declared itself, and to operate early before any routine treatment has been tried. For it is urged (1) that the disease is progressive and cannot be arrested; (2) that the kidneys are subject to back-pressure, which ultimately produces renal inefficiency and degeneration; (3) that the habitual use of the catheter invariably leads to sepsis, with local and general complications.

In reply to these arguments, it may be said that although the prostatic tissue may continue to grow, it does not follow that the resistance increases in the same proportion, and if it does, the resistance may be combated by a corresponding development of the bladder expulsive power (compensation); that there never can be any back-pressure if the catheter is properly and systematically used; and that the occurrence of sepsis is nothing more than the frank acknowledgement of a breakdown in the technique adopted with regard to the preparation and passing of the catheter.

In dealing with prostatic retention it would seem advisable first, if possible, to effect a cure, or an amelioration of the symptoms by treatment, and afterwards should this course fail or catheter life be too great a tax on the patient, then to resort to operation. The time lost will have no bad effect, in fact very often the reverse, and perhaps happily the patient may then escape the trouble of a severe ordeal.

The treatment of retention due to increased prostatic resistance should be directed to two main objects: first, to reduce that resistance, and secondly, to increase the expulsive power of the bladder.

No marked success, as a general rule, attends the treatment of the prostate alone, except in a limited number of cases, where the trouble arises either from congestion, possibly brought about by straining during the too frequent act of micturition, or from the pent up glandular secretion owing to the blocking of the slender prostatic ducts by debris or small calculi. Improvement may then be attained by appropriate massage applied directly to the prostate itself, the fluids are dispersed or expressed, slight shrinkage of the prostate follows, with a corresponding alleviation of the symptom. More, however, may be expected from a combination of this with treatment undertaken to restore or increase the muscular expulsive power. The procedure may be illustrated by describing a typical case. A patient complains of obvious and definite symptoms of prostatic enlargement accompanied by chronic retention. The urine is clear and healthy, and the prostate on rectal examination is found to be full and elastic. On introducing a catheter, immediately after he has passed all he can by his own efforts, 10 oz. of urine are withdrawn. The effect produced by the constant presence of this amount of fluid in the bladder is similar to that of a limb

subjected to continuous weight extension. It relaxes and loses its power; the loss and exhaustion in the bladder is accentuated by its struggle to expel a fluid against a resistance it cannot overcome. The amount of residual urine, if allowed to remain, tends to increase independently of any further increase in the prostatic resistance. It is evident, if any amelioration of the condition is to be effected, that the bladder must be artificially relieved of its load, and the catheter should be used certainly twice, if not three times, in twenty-four hours at regular intervals.

Under this treatment the symptoms disappear, and in the course of a few days the average residual urine falls from 10 to 7 or 8 ounces, but the quantity then remains stationary. The catheter has thus far restored some of the expulsive force, but will do nothing more, probably the reverse in the future, unless it is aided by some other means. For the urine is expressed from the bladder during catheterization only by the tonal pressure, and not by any muscular contraction. The muscle during the emptying remains idle, never being called upon to exert itself, and with such inaction, or with only passive movement, it soon begins to lose its power and become inoperative. To counter this defect, and to cope with the increased prostatic resistance, it is necessary not only to maintain the existing power by exercise, but also to develop muscle strength—that is, to produce compensation by hypertrophy. The line of treatment indicated is to induce the desire to micturate while the catheter is *in situ*. The urine is then expelled in a more rapid stream through the catheter, and probably at its side through the urethra, by the gentle muscular contraction, and not by tonal pressure alone, and thus the muscle is efficiently exercised.

This treatment must be repeated regularly and for a considerable period; the residual urine will gradually diminish, from 8 to 5 and from 5 to 2 ounces, and in quite successful cases total natural evacuation will result. There are, however, one or two details to which attention must be paid. In the first place it is not always easy to induce muscular contraction while the catheter is being used. The patient feels "no desire," and cannot evoke it. The best plan then is to pass the instrument when the bladder is full—that is, when it contains not only the residual urine, but also the amount he is able to void naturally. The desire then becomes almost spontaneous. Again, as the muscle grows in strength, more and more work must be imposed upon it, though it should never be overtaxed or exhausted. A catheter of a smaller internal bore than the original should be substituted, or the catheter should be drawn slightly into the prostatic urethra and the eye partly blocked. In both cases increase of flow of urine by the side of the catheter will follow. It is found, moreover, that a catheter, or "continuous" tube, is not absolutely essential to withdraw the residual urine when muscular contraction is induced; a solid instrument (a No. 6 or 7, especially if grooved on its surface) traversing the prostatic urethra will suffice, for it separates the passage walls and leaves a chink above and below it through which the urine will escape during vesical contraction.

CONCLUSIONS.

The objects, therefore, of instrumental treatment of a case of retention from prostatic enlargement are:

1. To preserve intact the activity of the existing muscle by exercise.
2. To prevent the exhaustion which must necessarily follow an ineffectual struggle, by the use of the catheter.
3. To artificially reduce the prostatic resistance while the patient is under treatment so that the bladder may be emptied by muscular contraction.
4. To develop the muscle by gradually increasing its work as it gains strength, so that ultimately the expulsive bladder power may be able to deal with the increased prostatic resistance without the aid of artificial means.

The success or failure of the treatment, however, must largely depend on the maintenance of the urine in a condition of sterility. Too much stress cannot be laid on this point. Nothing short of boiling both instrument and lubricant is of any avail. Chemical antiseptics are useless; but with this precaution, coupled with manual dexterity, an aseptic state may be maintained for an indefinite period.

RENAL DECAPSULATION FOR CHRONIC PARENCHYMATOUS NEPHRITIS.*

BY
FRANK KIDD, M.B., F.R.C.S.,

LONDON HOSPITAL.

In the early years of the present century this subject was "in the air," as a result of the writings of Edebohls of New York. At that time I was able to observe the results of stripping the capsule of the kidney in several cases of chronic nephritis. For some reason or other the results were not promising, and when one came to consider Edebohls's book, many of the cases quoted in the book did not appear to fit in with the conception of chronic nephritis as usually understood in England. At that time, therefore, I came to the conclusion that there was very little promise in stripping the kidneys for chronic nephritis.

In 1916 I had my attention called to this subject by the fact that I was called in to see the children of two doctors suffering from chronic nephritis. The doctors urged me to strip the kidneys. Not having had favourable experience of this measure I could not accede to this request, but I began to look up the recent literature again, and noted that favourable cases had been reported from time to time. I asked some of my medical colleagues to allow me to try the operation once more upon patients at the London Hospital. As a result, Dr. Lewis Smith and Dr. Hadley sent me the first case I report below. He had been ill for a very long time, was completely waterlogged, and medical treatment seemed to offer him no further hope. Soon after the operation I went away in the army and lost sight of the patient. He turned up in 1919 quite restored to health and able to do a full day's work.

I was so impressed with this that I asked Dr. Hadley to send me some more cases; the last three I report below. The results were that one appears already to be well, another improved for a time but relapsed, and shortly afterwards died of tuberculosis of the lungs and uraemia. The fourth lost all his signs and symptoms for a short time, but has since relapsed.

I think these results, taken in conjunction with Sir Thomas Horder's cases, justify an appeal to the profession to reconsider this subject, as it is clear that some cases of chronic nephritis are greatly benefited and may even be cured by the comparatively harmless process of stripping the capsules of both kidneys.

When we have a sufficient number of cases for review I think we shall be able to pick out a type case in which the result is likely to be beneficial. At present it does not seem possible to state which case the operation is going to benefit and which not. Sir Thomas Horder suggests that it is the case without cardio-vascular change that will benefit from the operation, but I do not yet feel convinced of that. Two of my patients had a high blood pressure and two a low blood pressure, and yet the result was quite good in one of the patients with high blood pressure. Of course, in this case, the raised blood pressure may only have been a temporary phenomenon, and it may be that no permanent changes had taken place in the heart or in the blood vessels. Still, I feel that there is something more we have got to find out to enable us to distinguish the type of case suitable for the operation. One favourable case had polyuria, and one had oliguria.

EFFECT OF DECAPSULATION.

How does stripping the capsule have a beneficial action? I cannot believe that it has anything to do with the relief of tension, because when one strips the capsule in these cases the kidney does not seem to be under any tension—that is to say, it does not expand; nor does the capsule appear to be capable of a great resistance to tension. We know how easily the capsule can stretch in cases of acute pyelonephritis. In such cases the kidney will suddenly swell up to two or three times its normal size, and return to the normal size again in a fortnight or less, so that the capsule must be easily distensible. I do not think it can be due to a permanent increase in the blood supply of the

kidney, because the favourable changes seem to appear within a few hours, or at most within a few days.

Personally I believe that by removing the capsule of the kidney we unblock the lymphatics and set up another route for the lymph to flow out of the kidney. The lymphatics of the kidney run up from the ureter under the capsule through the kidney, where they receive the lymph of the kidney substance, and then to the glands in the vascular pedicle of the kidney. The capsule seems to act as a membrane to shut off lymph from the perinephric fatty tissue. Possibly in these cases of chronic nephritis the lymphatics become blocked either by excess of lymph or by fibrinous deposit, and the nephritic poison cannot be drained away from the kidney substance. I have noticed that directly after stripping off the capsule of these kidneys, clear lymph seems to flow out from the kidney sponge almost at once—the kidney seems to ooze lymph. This lymph may then be picked up by the tissue spaces of the perinephric fat and be absorbed by another route.

Technique of Operation.

As regards the details of the operation, I always operate on the kidney with the patient in the face-down position, as recommended by Edebohls. In this position the patient breathes much better, and it is possible to expose both kidneys without moving the patient. There is no need whatever to bring the kidneys up to the surface; I simply cut down to the surface of the kidney, make a snick in the capsule and strip it off with the fingers, and leave it all bunched together round the hilum. I put in a tube for twenty-four hours. In this way I did both kidneys in twenty-three minutes in one patient and twenty-two minutes in another patient. I think it is of advantage to operate as quickly as possible, as one does not want to expose the patient for a long period to an additional kidney poison, such as ether or chloroform. One of the patients was so dyspnoeic that he could not lie down at all. The anaesthetic was administered sitting up, and when he was "under" he was placed in the face-down position and we found his breathing was good enough to proceed. The same evening the patient could lie down in bed and within a few days his dyspnoea had entirely disappeared.

SUMMARY OF CASES.

I give a summary of the four cases in which I have tried this procedure. I hoped to have operated on some more cases before I reported them, but I thought that this was a favourable opportunity to bring forward the work I had already done, in the hopes of encouraging further research on this subject.

CASE I.

Male, aged 14 years. Admitted, June 9th, 1915, to the London Hospital, under the care of Drs. Hadley and Lewis Smith. Has never had scarlet fever. Sudden onset of present illness a few days previously. Complaints of severe headaches and vomits intermittently. General oedema, extreme pallor; oliguria very pronounced, as little as 6 ounces of urine passed in twenty-four hours. Urine: Solid with albumin; specific gravity 1045; casts; no blood. Systolic blood pressure 120 mm. of mercury.

Shortly after admission had fever lasting a week, highest temperature 103° F. After ten weeks in bed on the usual medical treatment he showed evidence of improvement, and went out with very slight oedema of legs and a trace of albumin in the urine.

Relapsed March, 1916, after a chill. Readmitted June 8th, 1916. General oedema and pallor. Urine: Oliguria—8 to 12 oz. a day; solid with albumin. Systolic blood pressure remained at 115 to 120 mm. of mercury. Up to September 27th no improvement at all on usual treatment. No real dyspnoea.

September 28th: Operation under open ether. The right kidney stripped *in situ*. The kidney appeared moderately enlarged, paler than normal; it bled too freely, and was friable. The capsule stripped easily. No evidence of fibrosis. A rubber drain left in for a few days. October 25th: Left kidney stripped. November 1st: Urine $\frac{1}{2}$ albumin. November 14th: Urine $\frac{1}{2}$ albumin. Left hospital improved but by no means cured.

Seen again on May 1st, 1919. Appears to be in perfect health. Able to do a full day's work. Urine: Specific gravity 1010; a trace of albumin. No oedema, no pallor. Blood pressure normal.

When seen again on November 13th, 1919, was perfectly well.

CASE II.

Male, aged 27 years. Admitted to the London Hospital under the care of Dr. Hadley March 4th, 1920. Eight months previously attended Brompton Hospital for tuberculosis of the lungs; discharged improved in October, 1919. November 1, 1919, general oedema and pallor.

On admission general oedema and ascites, dyspnoea, anorexia and pallor; no fever; frequent vomiting. Urine: Albumin $\frac{1}{2}$; casts; blood; polyuria, 70 to 90 oz. a day; specific gravity 1011, urea 1.1 per cent. Optic discs blurred. Systolic blood pressure 175 to 180 mm. of mercury. The apex beat was in the nipple line in the fifth space.

* Contributed to the Urological Section of the Royal Society of Medicine, October 28th, 1920, following Sir Thomas Horder's paper on the same subject (BRITISH MEDICAL JOURNAL, November 13th, 1920, p. 727).

April 4th, 1920: Getting rapidly worse; orthopnoea; oedema of lungs; cannot lie down at all, and has to be nursed in a chair. On April 12th I persuaded Dr. Whyte, a resident, to administer ether to the patient in the upright position. As soon as the patient was "under" he was placed on his face over an air bag, in which position he was able to breathe sufficiently well for me to proceed with the operation. I stripped both kidneys in twenty-four minutes from the first cut to the last stitch. There was advanced oedema of the perirenal fat. The capsule was thin and friable, and very adherent to the kidney substance, and stripped badly. There was no shock, and the same night the patient was able to sleep quietly lying on his back, propped up by pillows. In a few days the oedema had much diminished and the dyspnoea had disappeared. The improvement was only maintained for a few weeks, and then the symptoms returned again, though the dyspnoea did not become so bad.

He went to the infirmary, where he died of phthisis and uraemia on September 6th, 1920. There was no post mortem examination.

CASE III.

Male, aged 18 years. Admitted to the London Hospital under the care of Dr. Hadley, June, 1920, with a history of six months' general oedema and pallor, and headaches.

On admission, general oedema, pallor. Urine: Albumin $\frac{1}{2}$; casts; polyuria, as much as 90 oz. in twenty-four hours. Systolic blood pressure 170 to 180 mm. of mercury.

Operation July 22nd, 1920. Dr. Whyte administered open ether. I stripped the right kidney in thirteen minutes, the left in nine minutes. Capsule stripped easily. Kidneys enlarged, pale and mottled and fatty. No oedema of perirenal fat. Lymph oozed out of kidney on stripping. Portion removed for section.

The patient improved at once. In October, 1920, he was able to go about and looked upon himself as well. There is, however, still a little albuminuria, and the legs swell very slightly at times.

CASE IV.

Male, aged 20 years. Admitted to the London Hospital July, 1920, under Dr. Hadley, with a history of general oedema since six weeks before admission.

On admission, general oedema, pallor not marked; no vomiting; no fever; no headache. Urine: Solid with albumin; specific gravity 1020-1025, oliguria, 18 to 32 oz. in twenty-four hours. Systolic blood pressure 130 mm. of mercury. No improvement after five weeks' medical treatment.

Operation on July 22nd, 1920. Dr. Probyn Williams administered ether. Each kidney stripped in eleven minutes. Fluid poured out of perirenal fat. Capsule thickened, stripped badly, and tore pieces of kidney out. Marked fibrosis. Kidneys not enlarged; capsule pale because of the oedema of capsule itself; the cortex appeared to show areas of fatty degenerations, but was not diffusely and completely degenerated as in the other cases.

Three weeks later the oedema had disappeared, the urine had increased to normal amount, and the albumin had diminished. The patient was getting up in September, but then got chilled when sitting about the ward, and relapsed.

RECONSTRUCTIVE ANEURYSMORRHAPHY IN THE THIRD PART OF THE AXILLARY ARTERY.

BY

C. JENNINGS MARSHALL, M.S., M.D., F.R.C.S.,

ASSISTANT SURGEON AND OPHTHOEALIST, KING'S COLLEGE HOSPITAL; SURGEON, MANOR HOUSE HOSPITAL.

A MAN, aged 25, wounded in March, 1918, was, after three months in hospital and *dépôt*, returned to his unit. He was demobilized in 1919, and resumed his occupation as a baker. At that period he had, at most, occasional aching in the axilla. In February, 1920, he noticed a swelling in the armpit which increased slowly in size; it was accompanied by a feeling of heaviness in the left upper limb after use. After a short time he began to experience pain radiating down to the index and middle fingers and to lose power in the index. After six months' delay he was admitted to the Manor House Hospital.

It was seen that the patient had sustained a through-and-through bullet wound of the left axilla. A fine scar above the lower margin of the pectoralis major one inch and a half from its insertion indicated the entry, and a slightly larger one a little outside the inferior angle of the scapula the exit. In the line of the artery was an aneurysm the size of a large walnut, its upper third lying under cover of the anterior axillary fold. The expansion was forcible, but not great in extent; the tumour could not be emptied by pressure owing to the pain referred to the index. There was no venous hum. The adjacent tissues were not thickened—the tumour was quite discrete—very little inflammation or effusion had evidently accom-

panied the wound. There was slightly impaired sensation of the ends of the index and middle fingers; flexion of the index was very weak. The peripheral circulation of the limb did not differ from that on the other side.

Operation.

Open ether was administered by Dr. Bookey, and Mr. A. E. Woodall, F.R.C.S. (resident surgeon), assisted.

The arm was fully abducted, and an incision four inches long was made in the line of the artery, its centre over the aneurysm, and its upper end curving inwards towards the chest wall. The deep fascia was divided to the full extent of the wound, and the axillary artery was exposed one inch above the upper limit of the aneurysm; the minimum amount of dissection was done to permit the application of a Clive's artery clamp at this spot. The vessel was then treated similarly below the sac; the two

clamps lay above the anterior circumflex and the profunda artery respectively. The aneurysm was next defined by sharp dissection. Only at the lower and inner part was there any difficulty; elsewhere the tumour required only a few touches of the knife to free it. When the vein had been separated at the lower and inner part it was seen that the inner head of the median was bound to the aneurysm by dense fibrous tissue; when this was divided, however, the nerve showed no break of continuity. The sac was then defined up to its point of origin from the artery, to which it was moderately adherent up to its neck, and then opened by a longitudinal incision. At once it became apparent that the collaterals needed control. The branches arising between the clamps were quickly defined by blunt dissection, the flow from the sac being checked by pressure, and a clamp placed to include them; very slight pressure secured complete haemostasis. The

opening from the artery was oval ($\frac{3}{4}$ in. by $\frac{1}{2}$ in.); at the junction of vessel and sac there was a ring of almost cartilaginous density, as became evident later on an attempt to pass the needle at this spot. The sac, which was free from clot, had the thickness of blotting paper; its interior looked smooth and shiny everywhere. Two branches had been clamped—the posterior circumflex just above the level of the opening, and the anterior at its lowest level, each at a part of the artery opposite to the opening into the aneurysm. A test was made to determine the relative importance of these in the collateral circulation. With the posterior vessel clamped the flow from the anterior was the feeblest possible trickle. That from the posterior was considerable, steady, and in quantity about equal to that from a radial vein.

It was estimated that to suture the edges of the opening, allowing for a fair depth of apposition of the intima, would diminish the diameter of the vessel, compared with the part above, to about two thirds, which seemed adequate. The sac was therefore cut away, leaving only a thin rim round the neck. The whole area was kept moist by normal saline. With a non-cutting fine needle a continuous suture was introduced, beginning above and finishing below the opening, passing through the arterial wall immediately adjoining the thick ring; the stitching was mattress in type, every other stitch returned slightly to give a locking effect. The material was very fine silk.

The clamp on the collaterals was then released and fairly free oozing occurred, the fineness of the silk having prevented any but the slightest tension in approximation. The clamp was again tightened and a stronger silk suture was introduced, the needle traversing the artery wall on either side and returning similarly through the rim of sac, thus embracing the hard ring and securing apposition of

its opposite sides. For further safety these stitches were made to cross in pairs. The clamps were released in order, first from the branches, then the distal, then the proximal, and, as the severest test, the distal clamp was tightened again. There was not the slightest oozing. In view of the exposure of the site of suture to strain, a graft of fascia lata was fixed as a collar round the vessel at this point, with its fibres transverse to the line of the artery, and with slits to allow the passage of the circumflexes. Above and below a loose stitch in the fascia near by prevented telescoping. The wound was then closed and dressed with gauze wet with 1 in 2,000 flavine. At the close of the operation the radial pulses were equal.

After-History.

Convalescence was uneventful. There was pain referred to the index and middle fingers for three days. The wound healed by first intention, and physiotherapy appropriate to the nerve condition and to the axillary scar was adopted from the twelfth day.

Three months later there was no sign of yielding; at the site of the suture was a thickening due to the presence of the graft. The brachial pulses were equal and the index showed almost complete recovery. Pulsation, though slight, indicated that thrombosis and obliteration of the artery had not occurred at the point of suture.

FRACTURE OF FEMUR: A SIMPLE METHOD OF EXTENSION.

BY

B. F. PENDRED, M.R.C.S., L.R.C.P.,

LOUGHTON, ESSEX.

FRACTURE of the femur in private practice is always looked upon with apprehension, and even in hospital work with some degree of anxiety.

One great reason for this attitude is the necessity for having a complicated apparatus made up of iron framework, a mast and guy-ropes, all requiring frequent adjustment and refitting, to the pain and distress of the patient. This, perhaps, may not be true of fractures below the middle of the shaft, as in these cases fair results may be obtained by use of foot extension with the limb lying straight along the bed.

The method I am about to advocate is for fractures above the middle, where the upper fragment is flexed forwards. As this fragment is too short to be maintained in any other position than that allowed by the muscles attached to it, it becomes necessary for the lower fragment to be brought into line with the upper, at the same time keeping up extension in that line. In such a case the patient is placed in bed on his back, the head and shoulders being supported by two or three pillows. The knee of the injured limb is raised until the femur is at the required angle, which is generally about 30 to 40 degrees to the horizon. It is maintained in this position with a knee pillow, or better still by a pyramid of sand-bags. A ring-shaped air-cushion is slipped over the foot, drawn up to the knee and inflated as fully as possible, the foot being allowed to fall back on the bed. A strong bandage is tied round the air-cushion exactly opposite the knee and the other end carried to a pole or mast fitted to the foot of the bed; strong traction is made in the line of the upper fragment, lower fragment, diameter of cushion, bandage and point on mast, until the ring becomes definitely oval, when the bandage is fixed to the mast. It will be seen that the extension is procured by a pneumatic pad in the flexure of the knee, and that the strain is transmitted to the femur through the head of the tibia and the ligaments of the knee-joint. These being rigid structures serve the purpose well.

Pneumatic pressure at the point indicated is justifiable, because all the great nerves and blood vessels dip deeply here under the heads of origin of the gastrocnemii, which being massive and fibrous in this situation are well adapted to support continuous pressure and protect underlying structures.

The advantages attendant on this method are:

1. Simple apparatus. A few pillows, a long piece of stick, a bandage and a ring air-cushion or inner tube of a motor tyre. Such things can be obtained almost anywhere at very short

notice, and there is no need to keep apparatus of various sizes in stock.

2. Ease of application. No skilled assistance required.

3. Once fixed adjustment is very seldom required. The bed-clothes are arranged so that the ring-cushion is uncovered and visible, a glance at its shape informs one immediately of the degree of tension and inflation.

4. The foot hanging over the pneumatic pad acts as a kind of rudder and prevents rotation of the lower fragment, or if desired it can be pushed inwards or outwards, rotating the lower fragment in any required direction.

5. There being no pulleys, guy-ropes, weights, or iron frame, there is very little necessity for disturbing the patient, which saves much anxiety and suffering. A bed slipper is easily adjusted.

6. The thigh is supported underneath by sand-bags, and others may be used at the sides if required to give a sense of security, but these are not necessary. The thigh can therefore be fully exposed, permitting easy examination, dressing or massage of suitable type, all without any disturbance of the fragments whatever.

I have treated only one case by this method:

A boy, aged 10 years, sustained a simple fracture of the right femur above the middle of the shaft. He remained in the apparatus for four weeks with the very slightest adjustments. At the end of that time, union being quite strong, the limb was removed from all restraint. At first any attempt to straighten the limb caused pain in the knee-joint, but full flexion and extension returned without assistance within forty-eight hours. The only evidence of pressure by the pneumatic pad was a very superficial blister, which no doubt would have been obviated by binding lint over the rubber before application. The shortening was under a quarter of an inch. At no time was there any numbness, tingling, or oedema of the leg or foot.

The extreme simplicity and efficiency of this method, as compared with many devices advocated, are my excuse for seeking publication.

AN UNUSUAL CASE OF MYELOCELE.

BY

A. J. COKKINIS, M.B., B.S. LOND., F.R.C.S. ENG.,

ILFORD.

In practically all the standard textbooks myelocoele is stated to be incompatible with life, the infant being either stillborn, or dying within a day or two. Bland-Sutton holds a somewhat different view. He states:

"Many children in which this condition is present are still-born: the few that survive their birth rarely live longer than three days, the continual leakage of cerebro-spinal fluid being sufficient to explain the invariable brevity of their lives." (*Tumours: Innocent and Malignant*. 1917.)

He thus admits the possibility of survival beyond the first day or two.

In inquiries, admittedly limited, which I have made on this subject, I have been unable to trace a single case in which the duration of life exceeded a period of three days. I have therefore thought that the following case, in which life was prolonged for twenty-three days, merited publication.

I was called to see the patient, a male infant, an hour after its birth, at the Ilford Maternity Home, during the early hours of September 18th, 1920. The reason for the early call was that the infant seemed very feeble and had difficulty in breathing. On arrival I found a well-nourished, good-sized baby, which soon revived and cried lustily. He had a well-shaped head, with no evidence of hydrocephalus.

The lower limbs were held rigidly flexed to a right angle at the hips, and rigidly and completely extended at the knees. The legs resisted straightening, and were paralysed, wasted, and, as far as could be made out, anaesthetic. There was double talipes equino-varus, the varus element markedly predominating, with a well-marked crease on the soles, corresponding to the transverse tarsal joint.

Looking at the back, there was a large, raw, circular area, somewhat depressed, and corresponding to a deficiency in the neural arches and failure of closure of the neural groove, opposite the lower three lumbar and upper two sacral bodies. The open spinal cord was seen in the middle line at the upper part of the defect, while the nerves of the cauda equina could be distinguished in the lower part. The myelocoele narrowed and deepened as it was traced upwards into the funnel-shaped termination of the central canal. Cerebro-spinal fluid was constantly, though slowly, dripping out of the apical opening, bathing the raw area, and then running in drops over the buttocks. The surrounding skin was rendered as far as possible aseptic, and a dressing applied. The next day the flow of cerebro-spinal fluid was freer, and some congestion developed round the myelocoele. During the first week the child's condition remained good. The raw area gradually contracted down and became deeper, while the inflammatory redness subsided.

The child now passed temporarily out of my care, being transferred to the Ilford Isolation Hospital. Here it was kept for several days, during which its condition was reported to be quite satisfactory. It was then sent back to the mother. When the child was over a fortnight old the mother naturally began to doubt the soundness of my prognosis, which had already been belied by the child living as many weeks as I had assured her was his maximum expectation of days. She expressed herself anxious for further advice, and I was making arrangements for the infant to be seen by Mr. W. H. Clayton Greene, when, during the third week, meningitis set in, and the little one died on October 11th in a storm of convulsions. It was thus twenty-three days old on the date of its death. Owing to the fact that both mother and child left the district a few days before the latter's death I was unable to witness the end. For the information about the date and manner of the infant's death I am indebted to Miss Roberts, the matron of the Maternity Home, who obtained it in a personal interview with the mother.

Another point arising in connexion with this case is the frequency of myelocoele when compared with the other types of spina bifida. Sir John Bland-Sutton is quoted by many authors as stating that myelocoele is the commonest variety of spina bifida; he admits, however, that of all cases that survive birth probably two-thirds are meningo-myelocoeles. Of the seven cases of spina bifida of which I have personal knowledge the one here described is the only case of myelocoele; one was a meningocele, one a spina bifida occulta, and the remaining four were diagnosed as meningo-myelocoeles. I have yet to see my first case of syringo-myelocoele.

In reference to the frequency of spina bifida in general practice the experience of a local practitioner of thirty years' standing is instructive. He has met with but two cases during this period in a practice which, to my knowledge, is exceptionally busy.

THE ACTION OF THE INTRINSIC MUSCLES OF THE FOOT AND THEIR TREATMENT BY ELECTRICITY.

BY

G. MURRAY LEVICK, M.R.C.S., L.R.C.P.,
ELECTROLOGIST TO ST. THOMAS'S HOSPITAL.

Most of the intrinsic muscles of the foot and the long flexors of the toes play important parts that do not seem to have been recorded. The flexors of the toes raise the longitudinal arch of the foot, because when the weight of the body is thrown forward, as the heel leaves the ground in walking, their action is to draw the heel towards the toes, acting as bowstrings across the arch from heel to toe. For this reason the correct way to land from a jump is to have the whole weight of the body borne between the balls of the feet and ends of the toes, and, when patients are doing this or being given heel raising exercises in the standing position, they should be told to "grasp the floor with the toes," which thus become the fixed points from which their flexors act.

Flexor brevis digitorum has the strongest arch-raising action, owing to its insertion into the second phalanges, placing it at a disadvantage in bending the toes compared with flexor longus. The flexors of the toes should be used to assist progression in walking fast or running, and most people use them for this purpose. They thus support the arch at the moment when the greatest strain falls upon it. Flexor brevis hallucis, pulling from the cuboid to the first phalanx of the great toe, probably assists considerably in supporting the transverse arch.

The transverse arch is maintained chiefly by the dorsal interossei, and this is their most important action. In a demonstration given recently at the Royal Society of Medicine, I think I showed this clearly, using the method I shall describe shortly, and giving a clear picture of these muscles with their bipennate origins, drawing the metatarsal bones together. To describe the action of one of these muscles will suffice to explain the action of the rest. We will consider the second metatarsal bone as the "keystone" and as the middle line. When the second

dorsal interosseous muscle contracts, it performs the following rôles, in the order given. These rôles have been carefully observed during electrical stimulation, first of individual muscles and then of the group as a whole.

1. Feeble contraction. Abduction of first phalanx from middle line.

2. Stronger contraction. Flexion of metatarso-phalangeal joint plus the pull on the extensor tendon. End of toe brought into contact with the ground. (In voluntary movement this contact is of course strengthened by the long and short flexors.)

3. Powerful contraction. The fixed points from which the muscle acts are now (a) the second metatarsal bone, (b) the insertion of the tendon into the first phalanx. As the muscle contracts, the third metatarsal bone is drawn towards the second—that is, towards the middle line. In voluntary movement the second metatarsal is fixed by the opposition of the first dorsal interosseous muscle, which also fixes the first phalanx of the second toe while it is drawing the first metatarsal bone towards the second, and so on. As each metatarsal bone is drawn towards the second, it is pulled into a plane below that of its more mesial neighbour, so that the second metatarsal—the keystone—is raised upwards. This movement is aided by the metatarsals being brought into line with the arch of the cuneiform bones.

The following is the method by which all the muscles I have mentioned may be exercised and brought into a state of efficiency, even when they are wasted and unhealthy from prolonged pressure and disuse. It demonstrates conclusively also the actions I have described above.

The foot is placed in an ordinary porcelain arm bath containing a sufficient depth of warm water to reach just below the external malleolus. The heel rests on a carbon electrode, to which is connected one of the terminals of a Smari-Bristow coil. Another carbon electrode, connected with the other terminal, is held in the left hand. It is dipped into the water in front of the toes. The right hand manipulates the core of the coil so that a surging faradic current is sent streaming through the intrinsic muscles of the foot. Experience will teach the operator how the position of the electrodes may be altered so as to obtain contraction of the different muscle groups at will, and their action is thus displayed in a particularly useful and pleasing manner.

As we proceed to carry out this treatment and place the electrodes in the required positions a clear view is gained of the transverse arch of the foot, rising and falling in time with the contraction and relaxation of the dorsal interossei. It is seen that this is a powerful action and emphasizes the importance of these muscles. The best position for the electrodes varies in different patients, but as a rule in treating the transverse arch I have them on each side of the front of the foot. The longitudinal arch, lateral and medial, is best operated with the heel on one electrode as first described. No stimulation of the long flexors takes place with this technique, and the action of the short flexors of the toes in raising the longitudinal arch will come as a complete surprise to those who see it for the first time, as it is so very marked. The long toe flexors and tibialis posterior can be stimulated in turn by detaching the cord from the electrode at the heel and fixing it to a disc electrode covered with a handful of wet lint so that it can be applied to their motor points, the other electrode occupying a suitable position in the bath. Flexor longus hallucis and flexor longus digitorum when stimulated in this way will be seen to raise the longitudinal arch to a very marked extent.

As to the indications for the application of the above technique as a method of treatment, these are several. It is applicable when the preliminary stages of flat-foot are curable by physiotherapy, and to the after-treatment of those more advanced cases which have been wrenched and fixed in plaster or have undergone surgical operation. Regarding the first class, there are many people walking about the streets suffering from what they describe as tender feet, and these people, experiencing pain on movement of the tarsal joints, avoid this as far as possible by planting their feet flatly on the ground with the toes pointing too far outward. This leads them through the successive stages of flat-foot.

Common causes of tender feet are deformity of the first metatarso-phalangeal joint owing to the fashion, common to almost the whole of civilization, of wearing boots shaped like a lead pencil, and, in women, the wearing of high

heels, because this tilts up the metatarsals at the back so that their heads press too much downward at the metatarso-phalangeal joints and cause sprains. The splinting of the foot in too tight a boot also causes atrophy of the intrinsic muscles from pressure and disuse, so that they become unhealthy and accumulate fatigue products and probably uric acid. The circulation of the whole foot becomes impaired in these cases, the tarsal joints suffering in common with the rest of the part. Walking in the manner above described entails the relaxation of all the arch-raising muscles, with obvious results.

Faradic treatment given in the manner I have explained yields surprisingly rapid results in such cases. The nutrition of the whole foot is quickly improved, and in most cases metatarsalgia disappears. As a preliminary to voluntary exercise after surgical operation it is highly to be recommended. It is waste of time, and discouraging to the patient, to begin re-education before these muscles are in at least a fair state of nutrition, and I regard it, after seeing the surprisingly good results that it yields, as essential in the satisfactory treatment of flat-foot. It is often impossible or extremely difficult to develop the small muscles by voluntary exercise alone. This applies especially to those cases that have been repostured by surgical methods, so that the muscles are relaxed after a long period of overstretching with the accompanying atony.

It is very important that the treatment should be given with care and intelligence, because the muscles are completely at the mercy of the operator, and treatment must progress by easy stages from a gentle beginning, otherwise the muscles will be over-fatigued and the condition aggravated. The contractions must be rhythmic, they must not last too long, and they must be divided by periods of complete relaxation. A Smart-Bristow coil is almost essential, as the best results cannot be obtained with the other coils in common use at the present time.

MEDICAL, SURGICAL, OBSTETRICAL.

LABOUR IN A CASE OF ENCEPHALITIS LETHARGICA.

THE following case came under our care at the Aberdeen Maternity Hospital, and as the condition seems to be very rare, these notes may prove of interest.

Mrs. L., a primipara, was admitted to the Aberdeen Maternity Hospital on February 12th, 1921, with the history that she had been suffering from "sleepy sickness" for ten days. The patient was stated to be nearly at term.

She was very drowsy, but could be roused to answer questions sensibly. She had a dull, vacant, mask-like facies, no wrinkle being present on the brow or face. The eyelids drooped, and could not be raised to the full extent. Movements of the face and tongue were sluggish, but there was no limitation of ocular movements and no nystagmus. Reflexes were normal with the exception of the knee-jerks, which were exaggerated, and the abdominal reflexes, which were absent. The pupils responded sluggishly to light. The patient was very constipated and the mouth was very dirty. The child was presenting by the vertex, and the head was engaging the brim of the pelvis; the foetal heart sounds were heard distinctly in the middle line below the umbilicus, and the rate was normal.

On February 13th the patient became restless and seemed less lethargic; attempts to bear down were noted. Shortly after this the membranes ruptured and the os was found to be fully dilated. Bearing-down efforts were poor during the second stage and seemed to be sluggish, but the patient did not seem to appreciate much pain, though when questioned she stated she felt the pains. The head was delayed at the outlet, owing as it seemed to insufficient expulsive powers; delivery was therefore completed with forceps under a very light anaesthesia of chloroform and ether. The child weighed 9 lb. 9 oz. The placenta came away thirty-five minutes later, and during this time the patient became very lethargic; this condition continued for twenty-four hours, and it was with great difficulty that she could be roused at all. During this time it was noted that the left pupil was smaller than the right, and that there was a left external strabismus; there was incontinence of urine. On being questioned she would stop in the middle of her answer and apparently go to sleep. On February 17th she became less lethargic and took at times some interest in life, displaying interest in the baby when it was shown to her. When questioned regarding it, she had no recollection whatever of the labour. The baby was quite healthy and showed

no signs of drowsiness or oligopnoea at birth or after. On the tenth day of the puerperium the patient was transferred to the City Hospital, her condition being much improved.

It will be seen that in this case pregnancy seemed to be unaffected by the disease, but the lethargy was exaggerated for the first few days after labour, and especially for the first twenty-four hours. The patient slept through the first stage of labour without giving any sign that labour was in progress, and the end of the second stage was delayed on account of defective expulsive efforts. The third stage was normal in every respect and no excess of blood was lost. The puerperium, except for the conditions noted above, was uneventful and the uterus underwent normal involution.

We are indebted to Professor McKerron for permission to publish this case.

HERPES AND VARICELLA.

THE following case illustrating the herpes-varicella association may be of interest to record for the following reasons: First, there seems no possible doubt as to the varicella infection having been passed on from the herpes case, as both patients were inmates of the same house, standing by itself right out in the country; moreover, during the possible incubation period of the varicella no visitors came to the house nor had any cases occurred in the neighbouring farms or villages as far as I could ascertain. Secondly, taking the incubation period of varicella as fourteen days it would appear that herpes can remain infectious for at least seven days from its eruption.

On January 27th I was called to see a girl aged 25 who was complaining of pain in the right iliac fossa, simulating appendicitis. On January 28th a few vesicles were noted in this area, and on the following two days a typical herpetic eruption came out over the right buttock, groin, vulva and inner side of thigh; there were no vesicles elsewhere on the body. Three weeks later, on February 18th, the patient's small brother, aged 4 years, developed the typical eruption of varicella; during the whole intervening period he had been in and out of his sister's room daily.

I might add that I was quite unable to elucidate the origin of the herpetic infection; the patient, however, worked in a clothing factory some four miles away from her home.

Desborough.

G. F. P. GIBBONS, O.B.E., M.B.Lond.

In view of the recent reports of the apparent relationship between herpes and varicella, the following cases appear worthy of note: During the first week in January, 1921, I saw a girl, aged 9 years, who had a typical varicella rash. One week later a younger sister was brought to me complaining of pain in the fifth right intercostal space, and on the following day there appeared a herpetic eruption confined to this region.

Both children soon got well, but during their convalescence a third child in the same house had an attack of varicella. There were no other cases of varicella which I attended at the time, so I was led to suppose that the herpes in the second case acted as a link between the two cases of varicella.

TREATMENT OF LOCAL LEISHMANIASIS.

THE note by Colonel Erskine Risk on the treatment of Baghdad boils by scraping (February 19th, p. 267) leads me to say that it is by far the most satisfactory method of treatment hitherto suggested.

During 1917 and 1918, while serving in Mesopotamia, large numbers of Indians suffering from these sores came under my care, and I had ample opportunity to observe the results of treatment. My routine treatment was to scrape the sores thoroughly with a sharp spoon, and then to cauterize the base with pure carbolic. I treated more than two hundred cases in this way, and the average length of time which elapsed before the sores were completely healed was seventeen days. I found that even the face healed more quickly than on any other part of the body after scraping.

As far as I could ascertain recurrences were very uncommon, and the scars left were far less obvious than when the sores had been treated by any other method. The secret of success lies in the thoroughness of the scraping, especially at the edges of the sore.

CHEMICAL ESTIMATION OF GASTRIC FUNCTION.

At the meeting of the Medical Society of London on February 18th, Sir W. HALE-WHITE presiding, a discussion took place on the chemical estimation of gastric function.

Dr. J. H. RYFFEL, in opening, gave a summary of chemical work on the stomach, and dealt in particular with the two test meals most generally used—namely, that of Ewald (tea and toast) and that of Boas (oatmeal gruel). After showing a large number of gastric-analysis charts, with the curves for acidity and for free hydrochloric acid, Dr. Ryffel summarized the results of his observations by saying that in carcinoma ventriculi the only distinctive type was carcinoma of the pylorus, with no free HCl, high mineral chloride, lactic acid, and blood with the "coffee grounds" appearance. Cases of carcinoma in which there was no gross obstruction were far less distinctive. Lactic acid

HCl was absent, and the physio-

as low, but this held good of many

Mineral chloride was nearly always

high, but it was occasionally high in other conditions with low HCl, such as pernicious anaemia. Occasionally in these cases the free and the active HCl were normal; the mineral chloride was high, but high mineral chloride might be found in ulcer of the body of the stomach, especially with regurgitation. The presence of blood would not distinguish from ulcer. Blood might be due to trauma during aspiration of the meal, and in this connexion he had found it necessary to insist on examination of the faeces for blood in every case. If blood in the gastric contents was due to slight trauma during aspiration, no blood would be found in the faeces; blood also might be found in the faeces when it was not appreciable in the gastric contents. Spectroscopic examination of the faecal extract for acid haematin and haematoporphyrin, in addition to the ordinary tests for blood, was very useful. In simple ulcer, especially ulcer of the body of the stomach, the HCl was not by any means always above normal, and here again the bleeding was capricious; blood might be absent from the stomach but present in the faeces, or absent from both. Whether the older form of test meal or the fractional meal were employed, cases needed to be further tested by the examination of the faeces for blood, and, of course, all such tests could only be usefully employed in conjunction with the clinical study of the case.

Dr. J. A. RYLE was specially interested in the diagnostic possibilities of the fractional method of gastric analysis, and thought it of first importance to keep the method as simple as possible. The fractional test meal might at a sitting definitely establish a diagnosis of pyloric stenosis. In active pyloric or duodenal ulceration a very striking curve was obtained. In all fractional tests it was of special importance that the resting juice of the stomach should be carefully examined.

Mr. E. C. DODDS said that valuable information might be obtained with regard to gastric secretion by taking the percentage or tension of the carbon dioxide in the alveolar air. He gave examples of the typical diphasic curve of tension of CO₂ obtained in taking the meal, and said that he believed the rise which was shown was gastric in origin, due to secretion of hydrochloric acid, and that the fall was due to gastro-intestinal secretion, probably pancreatic.

Dr. T. I. BENNETT urged that if any valuable estimate of gastric function was to be made, it must be made by some method which tested samples taken at every phase in the gastric scale. Any gastric test which was taken at a fixed point after the ingestion of a meal must be liable to grave fallacy, and in proof he showed curves illustrating the variation of gastric function at different times in normal persons.

Dr. R. L. MACKENZIE WALLIS also gave particulars of gastric tests and advocated the Ewald test meal, because it enabled a complete analysis to be made, not only of the total acidity and the free HCl, but of the mineral chlorides as well, and these mineral chlorides furnished a definite indication of regurgitation or neutralization such as was met with in carcinoma of the stomach.

Dr. G. GRAHAM wanted a more complete chemical analysis than was usual with the fractional test meal alone. One could not do a complete chemical analysis every quarter of an hour, but it should be possible to do a complete analysis at the end of the hour. If the test meal was going to be done it should not be started until it was certain that the patient was no longer constipated.

Dr. W. H. WILLCOX also urged the need for chemical accuracy with the test meal. In the fractional test meal one worked with such small quantities that there was considerable danger of error in the acidity and hydrochloric acid determinations thereby made. He thought that the fractional test meal had not completely supplanted the older method of the hour test, which remained a very valuable means for eliciting the condition of the stomach.

Dr. RYFFEL, in reply, agreed with Dr. Willcox that the old form of test meal was by no means outdone. Certainly it would be an improvement, if it were practicable, to combine the fractional method with the other. In answer to a question as to the usefulness of determining ferment activity, Dr. Ryffel said that he had done practically nothing in this line himself, being somewhat hesitant about accepting the idea that rennin determination would practically reflect pepsin.

HABITUAL DISLOCATIONS.

At the meeting of the Subsection of Orthopaedics of the Royal Society of Medicine on March 1st the subject of recurrent or habitual dislocations was introduced, and several cases were shown by Mr. O. L. ADDISON, Mr. H. A. T. FAIRBANK, and by others who took part in the subsequent discussion.

Mr. LAMING EVANS (the President) defined such dislocation as the condition of a joint which, after dislocation had occurred and had been reduced and had remained reduced, offered a subnormal resistance to redislocation, and in fact suffered repeated dislocations by slight force. The terms "recurrent dislocation" and "habitual dislocation" were accepted as synonymous, though the term "habitual dislocation" was the more accurate. Of these dislocations, that of the shoulder-joint was by far the most common, partly owing to the fact that 50 per cent. of all dislocations occurred at the shoulder, partly because of the methods of reduction in unskilled hands, partly because of defective after-treatment, and partly because of the pathological lesions inflicted by the original injury. Habitual dislocations might be due to osseous, capsular, ligamentous, tendinous, or muscular causes. The pathological lesions which might be present were most various, and this meant that on occasion different methods of treatment must be adopted. He divided the methods of treatment into five: (1) Palliative, by appliances of various material and design; (2) physiological, in the direction of increasing the tone of muscle, tendon, and ligament; (3) reefing operations upon the capsule, either by plication or by excision and overlapping; (4) repair of ruptured tendons and musculo-tendinous insertions; (5) muscle transplantation. A fair trial of mechanical support and physiological toning should be given in all cases before operative measures were adopted. Reefing operations had undoubtedly been followed by many successes and not a few failures. Muscle transplantation had been performed by detaching the posterior fibres of the deltoid, passing them round the neck of the humerus, and fixing them in front, so that they offered support to that part of the capsule which was weakened both in subglenoid and subcoracoid dislocations. Opinions differed with regard to the fate of the transplanted muscle. Some held that it retained its contractile power, others that it underwent fibrous degeneration and acted as an additional extracapsular ligament. He gave an account of a case of his own in which Clairmont's operation was performed six months previously, so far with a satisfactory result, although the shoulder had been dislocated very easily, even by the act of sneezing.

Mr. T. H. OPENSHAW said that about fifteen years ago a patient was brought to him whose right shoulder had been dislocated fifty times. He tried various expedients, but got no satisfactory results until he divided the subscapularis, and since doing so there had been no further dislocation. He was convinced that the cause of the dislocation in this instance was over-action of the subscapularis. He had done the same operation since in about ten cases with perfect results.

Mr. A. H. TOWN believed, as a result of electrical testing, that the piece of deltoid transferred retained its function; at least in some cases the transplant was not a dead mass. He instanced one case of his own in which Clairmont's operation had been done successfully: a woman who had had an innumerable series of shoulder dislocations, some of them induced by the act of sneezing, but comparatively painless, and capable of reduction without anaesthetic. No further dislocation had occurred during the four months since operation.

Mr. W. ROWLEY BRISTOW said that the use of the abduction splint had been urged in some quarters, but this was a very uncomfortable apparatus, and although there were occasions when it was absolutely necessary, it should be restricted, he thought, to such cases. As for the question of function of the transplanted portion of the deltoid muscle, the fact that in a particular case the transplanted portion responded to electrical stimulation was not proof. Such response would, he thought, occur in every case if a muscle were taken and a part of it divided. There was no time for the degeneration which would cut out the faradic response, and he would expect it to react to the faradic current for a period. Mr. Bristow went on to speak more particularly about recurrent dislocations of the patella. In the simplest of these cases a knee press or redevelopment of the internal vastus should be tried, and might suffice. There must be borderline cases, and one could imagine that the additional pull of a strong internal vastus might correct the tendency to outward displacement. A moderate ridge on the femoral condyle and a good vastus might suffice when a moderate ridge and a poor vastus would fail to prevent the patella riding out too far. The operative procedures were (1) the correction of knock-knee if present; (2) plecting of the capsule on the inner side, which he thought bound to fail; (3) shortening the quadriceps; (4) alteration of the line of pull of the quadriceps by transplanting half or the whole of the patella tendon to the inner side. He had adopted, in addition to the transplantation, a small bone graft after levering up the external ridge on the femur. He suggested that transplantation of the tubercle with a tendon attached was a better procedure than the transplantation of the tendon alone. He further suggested that the bringing forward of the external ridge in the outer condyle was a rational surgical procedure, and only added a few minutes to the time of operation, even when a small bone graft was driven into the femur.

TREATMENT OF STAMMERING.

At a meeting of the Edinburgh Medico-Chirurgical Society on March 2nd, Emeritus Professor F. M. CAIRD presiding, Dr. HAMILTON G. LANGWILL called attention to the valuable work on this subject by the late Professor John Wyllie, and to his classical book *The Disorders of Speech*. His own remarks were largely an exposition of the principles of Wyllie's treatment. But he suggested that the recent treatment of stammering as a war neurosis by psycho-therapeutic methods opened up a new line of treatment which might be useful. The condition was commonest in late childhood and early adolescence, and rarely developed after the age of 20; it was much commoner in boys than in girls, and imitation was sometimes a factor in causation. Wyllie described two main types—one a silent sticking at the utterance of particular sounds; and the other, and more frequent, where there was an audible check with the rapidly recurring utterance of a sound or letter. To the latter type the name "stuttering" was often given. Stammering nearly always disappeared in singing. There were three elements in speech—expiration, vocalization, and articulation—and the essence of stammering lay in an inco-ordination between the two latter, the fault generally lying in too much attention to articulation and in defective vocalization. It was all-important that the patient should

understand this double nature of his impediment, and, to make this clear, Wyllie used the simile of a violin where great stress was laid on the string hand, while the bow hand was neglected. Another great aid in treatment was the adoption of intoning, or the adoption of a different accent or tone of speech. Instruction must then be given in the physiological alphabet. The individual letters were to be separately practised, the general rule followed throughout of stressing the vocal element and touching lightly the articulating element. The vowel sounds gave little difficulty, but y and w, which were stepping stones between vowels and consonants, might give trouble. Thus "will you" should be practised as oo-ill, ee-ou. In the consonants, the voiceless ones, such as p, f, were more difficult for stammerers than the voiced, such as b, v, etc.; and the broad principle governing the practice of all letters was to touch as lightly as possible the voiceless initials and to emphasize strongly the vocal elements in letters. Examples of sentences for practice were given, these being constructed to contain the letters that were stammered, and being diligently practised with the teacher. The patient should stand up during practice, and should use a musical tone of voice. Patience, perseverance, and determination were essential for success.
